Plague (*Yersinia pestis*)

112

Walter Dehority • Gary D. Overturf

HISTORY AND EPIDEMIOLOGY

Yersinia pestis has been responsible for the most devastating epidemics in human history. Plague was first mentioned in 1320 BCE in the Old Testament in I Samuel. The first of three pandemics was heralded by the Justinian plague in northern Africa and the Mediterranean (541–700).^{55,73} The second pandemic occurred in Sicily in 1346. In the same year, plague appeared during the siege of Kaffa in the Crimea, thereafter spreading throughout most of Europe, where it became known as the “Black Death,” having been introduced by accompanying rodent populations from China along Asian-European trade routes. One-third of the population of Europe died in its aftermath. Between the 14th and 20th centuries, plague occurred throughout Europe and Russia, with resultant frequent outbreaks.⁴⁸

In 1894, Yersin and Kitasato, working independently, first described the plague bacillus while investigating plague spread from mainland China to Hong Kong,⁵⁴ and the role of rats and fleas in the spread of disease was defined.⁶⁷ In 1900, plague was introduced into San Francisco by rats aboard ships docking there and subsequently to ground squirrels and many other wild animals of the American Southwest.⁴⁵ In 1943, effective antibiotics against *Y. pestis* became available. Although antibiotics have been effective in the treatment and prophylaxis of plague, plasmid-borne antibiotic resistance is increasingly being noted.³² The potential for aerosolized *Y. pestis* as a biologic weapon has led to renewed interest in the understanding and study of this organism.³²

Plague is now a worldwide disease. The World Health Organization reported 38,359 human cases of plague from 1989 to 2003 with 2845 deaths.⁷⁵ Approximately 80% of the cases occurred in Africa, with endemic sites in east Africa and Madagascar; 15% were reported from Asia, including China, southeast Asia, and India; and 5% occurred in the Americas.⁷⁵ An African predominance continued into the first decade of the 21st century, with 97% of 21,725 cases reported originating from Africa, with the Congo and Madagascar reporting 82% of these cases.⁶ Plague remains endemic in the American Southwest, with more than 80% of cases occurring in New Mexico, Arizona, and Colorado and approximately 10% in California.^{11,14} Plague occurs in rodent populations of 17 contiguous states west of the 100th meridian.^{19,20}

BACTERIOLOGY

Y. pestis is in the family *Enterobacteriaceae* and is one of 14 *Yersinia* spp. It is a small, pleomorphic, nonmotile, gram-negative bacillus and is closely related to one of the three pathogenic representatives of the genus, *Yersinia pseudotuberculosis*.^{1,51,63,65} Wayson, Giemsa, and Gram stains of the bacillus take on bipolar or “safety pin” morphologic features.¹⁸ *Y. pestis* grows on blood, chocolate, and MacConkey agars at temperatures ranging from 0°C to 40°C (32°F–104°F); the optimal temperature is 28°C (82.4°F). On first isolation at 35°C (95°F) on 5% blood agar, the colonies are pinpoint in size, growing to 1 to 2 mm after 2 days. They are nonhemolytic on 5% sheep blood agar.⁶⁵

Depending on the clinical nature of the disease, blood cultures, sputum, or aspirates of enlarged nodes should be examined for typical bacilli. The isolated bacilli can be identified by the following criteria: *Y. pestis*, the sole *Yersinia* spp. that is nonmotile at 37°C and 22°C (98.6°F and 71.6°F), is the sole *Yersinia* spp. that is urease negative, but it may be positive in freshly isolated strains. The organism is positive for esculin, β -galactosidase, catalase, and methyl red. Oxidase, indole, and Voges-Proskauer reactions are negative. It ferments glucose, maltose, salicin, xylose, arabinose, dextrin, trehalose, and mannitol. It does not produce acid from lactose, sucrose, rhamnose, melibiose, ribitol, cellobiose, sorbose, or dulcitol. It does not use citrate, and it does not grow in potassium cyanide. *Y. pestis* is negative for lysine, ornithine decarboxylase, and arginine dihydrolase.^{49,65}

Positive cultures show pinpoint colonies within 24 to 48 hours after inoculation. Many laboratories use fully automated or semiautomated identification systems that may not detect *Y. pestis*, often confusing *Y. pestis* and *Y. pseudotuberculosis* or *Y. enterocolitica* with plague bacillus. Nonautomated laboratories may require 6 days to identify the organism. Currently because of the concerns for the use of plague as a biological weapon, suspected isolates should be referred to public health or other reference laboratories for final identification to the species level; this complies with the select agent requirements of the Title II Enhanced Controls for Dangerous Biological Agents and Toxins Act.³²

Several chromosomal-mediated virulence factors are responsible for the virulence of *Y. pestis*, including (1) an antiphagocytic capsular material known as fraction 1, (2) the endogenous purine synthesis that allows the organism to grow within macrophages, and (3) the ability to absorb iron from the medium.^{24,49,62,73} Several plasmids have been implicated in the development of other virulence factors.^{66,68,73} Several lines of evidence suggest proteins produced by *Y. pestis* may provide an immunomodulatory function, attenuating the human immune response to provide a more favorable environment for the organisms' survival.^{50,66} A prolonged immune response to the F1 antigen is common in survivors of plague and has been documented to persist for at least 10 years.³⁹ A plasmid of 9-kb pairs contains the determinant of secretory protein that kills other bacterial strains. A plasmid of 72-kb pairs, which all pathogenic *Y. pestis* strains contain, confers the requirement for environmental calcium to be present for the organism to grow at 37°C (98.6°F). When grown under this condition, *Y. pestis* produces V and W antigens that are necessary for virulence.²⁴ An exotoxin and an endotoxin have been found to contribute to the lethal effects of plague as well.^{65,71}

TRANSMISSION

Host

More than 200 mammalian species have been reported to be naturally infected with *Y. pestis*. Epidemics of plague usually are transmitted by fleas of infected domestic rats, which is more likely to occur in urban, rat-infested, and crowded dwellings. In the United States, plague is transmitted sporadically to humans after contact with an enzootic sylvatic focus.³⁴ Infected wild rodents perpetuate the plague bacillus in a given

ecosystem by virtue of their ability to withstand an inoculum of *Y. pestis* many times greater than that necessary to cause disease in humans or domestic animals. After inoculation, wild rodents may become bacteremic and infect fleas that feed on them; these fleas transmit the plague bacillus to another rodent. Hibernating animals are especially resistant to clinical infection. Animals inoculated before going into hibernation may survive through the winter and not die until after they come out of their burrows, reintroducing the bacillus in the new season.²⁹ Carnivores are relatively resistant to infection but contribute to the spread of the organism by transporting infected fleas from one area to another.^{34,67}

The role of domestic animals in bridging the gap between sylvatic plague and human infection has been studied extensively.^{47,54,60} Cats and dogs are susceptible to natural and experimental plague.⁶⁰ Epizootics in cats have been observed in conjunction with plague epidemics in humans.⁵⁴ Experimentally infected cats develop severe systemic illness, with bacteremia and abscess formation at the site of inoculum. Between 1977 and 1998, 23 cases of feline-associated human plague in the United States were reported²⁵; five cases were fatal; two of the patients had primary pneumonic plague, and one had septicemic plague. Many of these cases were misdiagnosed at presentation, leading to delays in treatment and, in some cases, fatalities. This diagnosis should be considered especially in the western states of Arizona, California, Colorado, and New Mexico. No seasonal variation in the occurrence of cat-associated illness was noted.^{20,25} Ten other cases reported in the literature of feline transmission of plague to humans involved four veterinarians.²¹ Dogs also are susceptible, but the disease is milder.⁶⁰ Dogs are less likely to transmit plague to humans, though this has been documented on five occasions in the literature.⁵⁸ Swine are resistant to plague disease, the only evidence of subclinical infection being the presence of antibodies to the fraction 1 antigen of *Y. pestis*. Domestic animals, by virtue of their intimate contact with wildlife and humans, may be responsible for some cases of human plague. This danger is accentuated by a dearth of symptoms in some animals.⁴⁷

Vector

Plague is transmitted to humans by bite of an infected flea, the skinning and evisceration of infected animals,³⁵ or inhalation of infected droplets from a case of pneumonic plague.⁴² Infrequent portals of entry include the conjunctiva⁴⁷ and the pharynx.^{46,56} *Y. pestis* has been detected in both head and body lice recovered from patients with suspected plague in the Democratic Republic of the Congo, leading to speculation that transmission could occur through lice as well as flea vectors.⁵³

The efficiency of fleas as vectors for human disease depends on the likelihood that an infected flea will feed on a person and that the flea will regurgitate bacilli into the victim's bloodstream in the process of feeding.³⁴ Flea species vary in both of these attributes. Wild rodent fleas are reluctant to feed on humans and do it only under duress (e.g., when the natural host dies). Fleas of domestic animals are more likely to bite humans. The Oriental rat flea, *Xenopsylla cheopis*, is the most efficient transmitter of plague because of its willingness to bite people and its propensity for regurgitating large numbers of bacilli in the process.³⁴ When the Oriental rat flea ingests infected blood, the actions of a coagulase produced by *Y. pestis* and a trypsin-like enzyme present in the flea's stomach result in the formation of an infected clot that blocks the flea's proventriculus. In obstructing the flea's intestinal tract, the clot allows further replication of bacteria. When the flea tries to feed again, it regurgitates large numbers of plague bacilli. The formation and dissolution of the fibrin clot are temperature dependent. At temperatures greater than 27°C (>80.6°F), a fibrinolytic enzyme is activated that dissolves the clot and allows the flea to dispose of plague bacilli. One postulation is that this temperature-dependent phenomenon is responsible for the observed cyclic nature of urban plague epidemics, which tend to subside with the advent of hot weather.⁸ However *X. cheopis* fleas with a blockage in the proventriculus are inefficient transmitters of plague given the long (12- to 16-day) extrinsic incubation period before blockage and transmission occur, followed by the death of the flea after a relatively short infectious window. This model may not adequately explain the rapid spread of disease often seen in epidemics of plague. However *Oropsylla montana*, a primary vector of

Y. pestis in North America, rarely becomes blocked after feeding and has a very short extrinsic incubation period (24–96 hours).²³ This flea is subsequently able to transmit *Y. pestis* in a murine model with 83% to 100% efficiency only 1 to 4 days after feeding, which may better explain the rapidity with which epidemics of plague may spread.²³ Fleas in which the intestinal tracts do not become blocked may also contribute to the endemicity of plague by harboring the organism and transmitting it in sublethal doses.⁹ Sylvatic plague depends on the rodent flea as the vector. This flea, although not as efficient as the rat flea in transmitting the bacillus, may itself become a reservoir of *Y. pestis* by surviving for 12 to 15 months after the original host dies. In the new season, it reintroduces the plague bacillus into a new rodent population.⁵⁴ The observation that *Y. pestis* can survive in soil between epizootics suggests another possible mechanism of transmission of plague.²⁷

EPIDEMIOLOGY

Recent studies have suggested that plague is an ancient disease of mammals; the bacterium emerged 1500 to 20,000 years ago as a clone that evolved from *Y. pseudotuberculosis* that first caused outbreaks in Africa.¹ Plague bacteria exist in enzootic cycles involving wild animals or domestic rats. In urban plague, the course of events usually is initiated by the introduction of plague from an enzootic focus into a susceptible rat population. With humans and rats living in proximity, an epizootic in rats may be followed by an epidemic in humans.⁵⁴ The epidemic may subside with the advent of hot, humid weather⁸ or the obliteration of the rat population.⁵⁴ Such epidemics rarely occur today but have been described in Southern Vietnam^{5,37} and more recently in India.¹⁶ Between 1985 and 1999, 23 countries reported a total of 29,020 cases of plague to the World Health Organization, with an average mortality rate of 11%; major epidemics and outbreaks occurred in Tanzania (1991), Zaire (1992, 1993), Peru (1993, 1994), India (1994), and Madagascar (1995), with fatality rates ranging from 4.6% to 22.3%.⁷⁴

In the United States, humans become infected most frequently by direct contact with a sylvatic reservoir of infection. Sporadic human cases usually result from working or hunting in a plague-infested area³⁴ or living near foci of infection as suburban spread encroaches on the natural habitats of rodents.¹³ Although poor socioeconomic status has been associated with an increased incidence of plague, particularly in resource-limited settings, recent analyses from New Mexico suggest that this is changing in the United States. Prior to 1990, plague cases clustered in regions with poor housing conditions, older homes, and high proportions of the population living below the poverty line.⁶¹ In the past two decades, plague is increasingly clustered in regions with newer homes, higher home values, and in areas of higher median income.⁶¹ This is presumed secondary to migration of upper- to middle-class families to regions ecologically supportive of sylvatic plague. Hence epidemiological suspicion of plague should primarily be driven by local epidemiological data and ecological factors, not socioeconomic considerations.⁶¹

In recent years, domestic animals, especially cats, have been responsible for a significant proportion of human cases. Sylvatic plague epizootics occur in the summer, and most cases of rural plague occur between April and September. The rare occurrence of human plague in the winter usually is associated with hunting and direct exposure to infected animal tissues.^{12,35} Many resurgences of plague occur after ecologic changes resulting in population increases in ground rodents such as prairie dogs, ground squirrels, mice, and rats in the American Southwest.⁹

The continental United States has a large enzootic focus that includes 130 counties in 15 western states. Surveillance for plague in rodents during the 1990s has identified infected animals farther east than ever before reported. The plague bacillus now has been isolated in wild rodents in eastern Montana, western Nebraska, western North Dakota, and eastern Texas.¹³ A summary of all 1006 human cases of plague in the United States reported to the US Public Health Service (1900–81) or the Centers for Disease Control and Prevention (1981–2012) revealed plague cases in 18 states.³⁶ Overall the median age was 29 years, with 65% of patients male; 82% of cases were bubonic, 10% septicemic, 8% pneumonic, 1% pharyngeal, and two cases (<1%) were gastrointestinal.

Approximately half of all cases occurred prior to 1925 and were primarily clustered around port cities, with tremendous variation in yearly incidence. The median age of patients was 30, with 71% male and just over 30% of Asian descent. The last case of confirmed person-to-person spread of pneumonic plague was documented in 1924. Four percent of cases were reported from 1926 to 1964, with just over half of cases (52%) reported from California; no cases were reported in 17 of these years. The median age was 15 years during this time period, with 83% of patients male and 83% white. Forty-seven percent of all cases occurred from 1965 to 2012, with approximately 90% of reports originating from the Southwest (54% of which were from New Mexico). In contrast to the preceding era, at least one case was reported in every year during this time period. The median age of infected patients was 28 years, with 57% of patients male and 33% of Native American descent. Many patients were infected within 1 mile of their residence and almost all within their state of residence.³⁰ Seven of the 10 patients described in 1993 were exposed in their home sites, and one, a veterinarian, was exposed at work.¹³

Occasionally plague has been acquired by a traveler in an endemic area who then traveled during the incubation period to a plague-free region of the country. This set of circumstances demonstrates why all physicians need to be aware of the presenting symptoms and signs of plague and to obtain an accurate travel history.³⁸ Laboratory-acquired infection with *Y. pestis* in laboratory workers has also been described, including two fatal cases.⁵⁷

PATHOGENESIS AND PATHOLOGY

The portal of entry of the plague bacillus determines, to some extent, the form of disease. The most common portal of entry is the skin when it is bitten by an infected flea. Broken skin may provide access for direct inoculation while infected animals are being handled. After overcoming the skin barrier, the organisms move through the lymphatics to the regional lymph nodes, where they elicit an inflammatory response. The infection may be localized at this site, with subsequent formation of antibody and recovery. This clinical form is known as *pestis minor*. The bacillus commonly is disseminated through the bloodstream. Distant organ involvement may include the liver, spleen, kidneys, lungs, and meninges. Disseminated intravascular coagulation is common in fatal cases. Coagulation defects, including thrombocytopenia and elevated fibrin split products⁵ and fibrin deposits in the glomeruli^{24,54} may be present. Bacteremia is not synonymous with severe disease and occurs commonly in mild cases.⁵⁴

The major determinant of severity seems to be the presence of high levels of endotoxin. The toxin of *Y. pestis* has the biologic properties of a typical endotoxin. When injected into experimental animals, it can cause clinical symptoms, signs, and pathologic changes characteristic of endotoxic shock and death. The quantity of endotoxin necessary to kill is estimated to be comparable to that present in a lethal dose of live bacteria.^{2,71} The murine toxin of *Y. pestis* has a direct inhibitory effect in vitro on the respiration of heart mitochondria of rats and mice, whereas it has little or no effect on the mitochondria of rabbits, chimpanzees, dogs, and monkeys. The differing sensitivities in vitro correlate with the susceptibilities in vivo of these species to *Y. pestis* infection.⁵⁹ Achieving high levels of toxin depends on the ability of the bacillus to replicate in the infected host. Although resistance to phagocytosis had been assumed to be related to virulence, experimental evidence has shown that virulent *Y. pestis* organisms are phagocytosed, but, in contrast to avirulent ones, are not killed. They continue to replicate freely in macrophages, allowing the accumulation of endotoxin.^{33,59}

When the lung is the portal of entry, the disease usually is more fulminant. After being inhaled, bacilli replicate freely in the alveolar spaces. Severe pneumonia, endotoxemia, and septicemia ensue and, if untreated, cause death. In fatal cases, the thoracic lymph nodes have infarction, necrosis, and liquefaction with pus formation. Edema and inflammation of surrounding tissue are common.⁵⁴ The mucosa of the trachea and bronchi is covered by bloody, frothy exudate. Submucosal hemorrhages and areas of necrosis may surround the trachea. The pleural surfaces contain hemorrhagic lesions and fibrinous adhesions. Lung parenchyma may be consolidated or show signs of acute edema.⁵⁴ The

predominant histologic feature is an alveolar exudate consisting of histiocytes and polymorphonuclear leukocytes.²⁴

Other organs also are involved. The kidneys may appear grossly hemorrhagic and contain areas of necrosis. Microscopic examination reveals leukocytic infiltrates of congested veins and capillaries. Glomeruli with fibrin thrombi frequently are found in patients with disseminated intravascular coagulation.²⁴ Biopsy of purpuric skin lesions reveals subepithelial hemorrhages and fibrin deposit in capillaries. These changes are indistinguishable from changes seen in a generalized Shwartzman reaction.⁵

CLINICAL MANIFESTATIONS

The incubation period of *Y. pestis* generally is 3 to 4 days but ranges from a few hours to 10 days. The onset of illness usually is abrupt, beginning with fever, malaise, weakness, and headache.^{54,55} Fever is high, frequently accompanied by shaking chills.⁴⁷ The appearance of a visible and palpable bubo may be preceded by pain and tenderness at that site.⁵⁵

On physical examination, the patient is "toxic," apprehensive, and tachycardic. The skin inoculation site may not be evident or may be marked by an abscess. In bubonic plague, typical large, fixed, edematous, and exquisitely tender nodes are present at one anatomic site.³⁷ In decreasing order of frequency, the areas of nodal involvement are the groin (femoral and inguinal nodes), axilla, and neck.⁵⁴ Any lymph node may suppurate, sometimes presenting an atypical picture (e.g., if intraabdominal nodes are involved, an acute abdominal emergency may be suspected).⁵⁵ Septicemia as an initial presentation of *Y. pestis* infection is common.³⁰ Among 71 confirmed cases of plague in New Mexico from 1980 to 1984, 25% presented without adenopathy. All patients with septicemia presented with fever and chills, and most had tachycardia, tachypnea, and relative hypotension. Seventy-two percent had gastrointestinal symptoms. Plague pneumonia was twice as likely to occur among septicemic patients as among patients with bubonic plague. Septicemic patients were significantly older and more likely to die than were patients with a bubonic presentation. Although septicemic plague occurred more often in older patients, those younger than 30 years with a septicemic presentation were more likely to die.³⁰

As a result of its nonspecific presentation, septicemic plague is difficult to diagnose early. Of 27 patients with plague admitted to Indian Medical Center in Gallup, New Mexico, between 1965 and 1989, five had a nonspecific febrile syndrome with upper respiratory tract symptoms and were prescribed penicillin; three of these five patients died. Another five patients had a nonspecific febrile syndrome associated with chills, myalgias, and anorexia. These patients were not treated initially with antibiotics, and three died.²¹ The index of suspicion must be high because early diagnosis is imperative to avoid a high risk of mortality. Individuals who appear to have community-acquired, gram-negative sepsis who reside in or have a history of recent travel to endemic areas of plague must be evaluated for and treated with antibiotics effective against *Y. pestis*.⁴⁵

Gastrointestinal symptoms often occur in patients with plague, especially patients with septicemic plague.²⁹ Between 1980 and 1984, more than half of the 71 patients with plague in New Mexico had gastrointestinal symptoms. In bubonic cases with these symptoms, 39% of the time the symptoms preceded the appearance of the buboes.²⁹ Common symptoms are abdominal pain, nausea, vomiting, and diarrhea. These symptoms are believed to be a general response to gram-negative septicemia. Occasionally, hepatosplenomegaly and mesenteric or retroperitoneal lymphadenopathy have masqueraded as an acute abdomen.^{31,38}

Neurologic manifestations caused by the effects of toxin on the brain are common. A patient with plague may have insomnia, delirium, stupor, weakness, staggering gait, vertigo, disorders of speech, and loss of memory.⁴⁴ *Y. pestis* meningitis is rare. Children younger than 15 years appear to be more susceptible, and septicemic patients are four times more likely to develop meningitis than are patients with bubonic plague.⁴⁴ It often manifests while the patient is well into a course of antibiotic therapy for bubonic or septicemic plague.³ When intravascular coagulation supervenes, renal involvement may manifest as acute cortical or tubular necrosis. Hepatic involvement may be evidenced by mildly

elevated liver enzymes.⁵⁴ Hantavirus pulmonary syndrome may mimic septicemic or pneumonic plague; both share a similar geographic distribution, and patients for whom this diagnosis is contemplated should be treated with antibiotics to cover the possibility of plague.⁵²

Primary pneumonic plague has similar constitutional symptoms but follows a fulminant course with a more pronounced pulmonary component. Within 20 to 24 hours after the onset of the illness, tachypnea, dyspnea, and cough productive of bloody, mucopurulent sputum supervene. If early and effective treatment is not instituted, the patient usually dies.⁵⁴ In the preantibiotic era in the United States, 18% of pneumonic plague patients transmitted *Y. pestis* to at least one other person.²⁸ No confirmed secondary transmission of pneumonic plague has been reported since 1924.³⁶ A potential case of human-to-human spread of pneumonic plague was reported in Colorado in 2015, but proved difficult to confirm given that the patient had contact with both an infected dog and a patient with pneumonic plague.⁵⁸

DIFFERENTIAL DIAGNOSIS

Because of the rare incidence of plague today, the diagnosis often is delayed or missed. Bubonic plague may be confused with other diseases affecting the skin and lymph nodes. The diagnosis of staphylococcal or streptococcal adenitis can be established easily by culture. Lymphogranuloma venereum is more indolent, has milder systemic symptoms, and is associated with anogenital ulcer. Syphilitic adenitis usually is nontender. With cat-scratch disease and *Pasteurella multocida* infections, the constitutional symptoms are few and the patient typically has a history of animal exposure. Tularemia has a more gradual onset.⁵⁴ In their later stages, the ulcerated skin lesions of plague may resemble anthrax.³⁷

DIAGNOSIS

The most important factor in promptly establishing the diagnosis of plague is having a high index of suspicion. Suspicion should trigger immediate notification to the local or state health department. The state reference laboratory can arrange for rapid and confirmatory diagnostic tests. Bacterial staining of lymph node material by Giemsa, Wayson, or Wright stain may reveal typical bipolar plague organisms. In the septicemic form of the disease, similar bacterial staining of venous blood frequently permits visualization of the plague bacillus.⁴³ Although culture is a mainstay of diagnosis, *Y. pestis* isolates may be misidentified by automated bacterial identification systems as a variety of gram-negative organisms (often with a high probability), including *Acinetobacter* spp., various species of *Pseudomonas*, and *Y. pseudotuberculosis*.⁶⁹ Hence clinical suspicion is essential when interpreting blood culture results from automated systems with gram-negative rods in patients with the possibility of plague.⁶⁹ *It is essential to inform the laboratory that plague is suspected.* Fluorescent antibody staining of direct smears and tissues may provide a rapid, presumptive diagnosis of plague.³² More recent rapid tests, such as an enzyme-linked immunosorbent assay for the F1 antigen¹⁷ or polymerase chain reaction for F1 antigen genes (*pla* and *caf1*), are now often available in public health laboratories.⁶

TREATMENT

Therapeutic decisions cannot await culture results. All patients suspected of having plague should receive prompt antimicrobial therapy after appropriate blood and tissue samples have been obtained for cultures, fluorescent antibody staining, and serologic testing.

The sulfonamides and streptomycin proved effective when they were first introduced in the 1940s. Resistant strains to one or the other of these antibiotics soon appeared.^{7,56} Despite the paucity of published trials in humans on antibiotic effectiveness, other than streptomycin and tetracycline, the Working Group on Civilian Biodefense Consensus Statement³² recommends gentamicin as an effective alternative to streptomycin for patients needing parenteral antibiotics. Gentamicin has been used frequently in recent years and has shown comparable outcomes to streptomycin in one case series.⁴ In vitro and in vivo studies in mice corroborate its effectiveness against *Y. pestis* infections.^{64,65}

For acutely ill patients thought to have plague infection, streptomycin or gentamicin are the drugs of choice. If available, streptomycin is given intramuscularly, 20 to 40 mg/kg per day in two divided doses up to a maximum of 1 g every 12 hours.⁴⁴ Gentamicin is administered intravenously or intramuscularly, 7.5 mg/kg per day to children and 3 to 5 mg/kg per day to adults in three divided doses. Although single daily doses of gentamicin are commonly recommended today and may be effective in infections due to *Y. pestis*, they have not been studied to date. During the first 36 to 72 hours after infection, *Y. pestis* invades host macrophages to evade innate immune responses. This intracellular state may result in an organism less susceptible to commonly used antibiotics than the extracellular form of *Y. pestis*. Indeed, minimum bactericidal concentrations (MBCs) for ciprofloxacin, chloramphenicol, gentamicin, and doxycycline are 2 to 4 times higher for intracellular than for extracellular forms of *Y. pestis*, whereas MBCs for streptomycin are unchanged.⁷²

Antibiotic susceptibility testing should be done because *Y. pestis* with plasmid-mediated, multiple-antibiotic resistance has been described.²⁶ The antimicrobial efflux pump AcrAB-TolC mediates resistance to many antibiotics commonly used for the treatment of *Y. pestis*.⁴⁰ Though plasmid-mediated multidrug resistance has been documented in *Y. pestis*, a 2012 analysis of 392 isolates from humans, animals, and fleas collected from 17 different countries failed to document any resistance to gentamicin, streptomycin, tetracycline, doxycycline, ciprofloxacin, levofloxacin, chloramphenicol, or trimethoprim-sulfamethoxazole (TMP-SMX), indicating that such resistance may be uncommon.⁷⁰

When plague meningitis develops, chloramphenicol, 50 to 100 mg/kg per day intravenously in four divided doses (maximum dose, 4.0 g/day), is the treatment of choice. Duration of therapy is determined by the length and severity of the illness. Treatment is continued for at least 7 days in patients with uncomplicated disease.¹⁵ Patients older than 8 years who do not require hospitalization may receive tetracycline at a dose of 25 to 50 mg/kg per day every 6 hours up to a total daily dose of 1 g in children and 2 g in adults. When outpatient treatment is given, the patient should be observed closely for the first 3 days to ensure resolution of the disease.¹⁵ In vitro data suggests that moxifloxacin at a dose of 400 mg/day may also be effective in the treatment of *Y. pestis* in adults.⁴¹

Sulfonamides may be used for prophylaxis in pediatric patients as an alternative to the tetracycline class of antibiotics, and, as noted under prevention, TMP-SMX is now currently recommended for prophylaxis in young children.³² Doxycycline at a dose of 4 mg/kg per day (up to a maximum of 200 mg) divided into two doses may be substituted for tetracycline.

PROGNOSIS

An analysis of all 1006 cases of human plague reported in the United States from 1900 to 2012 revealed that, prior to the use of antimicrobial therapy, 66% of cases overall were fatal, with higher mortality rates for septicemic (89%) and pneumonic plague (93%).³⁶ In the antibiotic era, mortality overall decreased to 16%, with a significantly lower mortality rate among those patients who received at least one dose of an appropriate antibiotic compared with those who did not (9% vs. 52%). In the antimicrobial era, the mortality rate for pneumonic plague (36%) remained higher than for septicemic plague (27%) and bubonic plague (13%).³⁶

With prompt specific antimicrobial therapy, the overall mortality rate for plague has decreased to 5%.⁴² Complications during convalescence include polyarthritides, small lung abscesses, delayed suppuration of buboes,³⁷ and meningitis. *Staphylococcus aureus* and *Pseudomonas* spp. may superinfect involved lymph nodes.⁵⁵ Immunity usually ensues after clinical or asymptomatic infection occurs, but natural reinfection rarely has been observed.⁵⁵

PREVENTION AND CONTROL

Institution of hygienic measures and eradication of rats from areas of human habitations have all but eliminated epidemics of urban plague. When epizootics occur in wild rodents, control measures must be directed

against rodents and fleas. Vector control can be achieved by the use of insecticides in fields and housing areas. In plague-endemic areas, the public must be instructed to avoid burrows, not to handle sick or dead rodents, to de-flea household pets, and to eliminate trash near living areas.¹⁰ Immune surveys of wild or domestic animals can be used as a surveillance tool to ascertain the presence of *Y. pestis* in the community because dogs, cats, and swine develop antibodies to the fraction 1 antigen of *Y. pestis*.^{47,60}

Patients with plague should be isolated with respiratory precautions until they are bacteriologically sterile. Close contacts of patients with pneumonic plague should receive chemoprophylaxis with tetracycline at 25 to 50 mg/kg per day up to 2 g in adults and up to 1 g in children 8 years and older. Younger children should receive TMP-SMX at 8 mg/kg per day (trimethoprim component) in two equal doses orally.³² The 6-day quarantine period for international travel for contacts of patients with plague does not guarantee the clearance of the bacillus from asymptomatic pharyngeal carriers.⁷ Public and professional education in endemic zones is paramount for ensuring prompt reporting of human and animal cases.

Plague vaccines have been used since the late 19th century for individuals at high risk for occupational exposure. They are no longer being manufactured in the United States. Research in this area is continuing.^{32,63}

Other *Yersinia* Species

113

Charles R. Woods Jr

Yersinia spp. are gram-negative, coccobacillary organisms that are primarily zoonotic. The genus is a member of the family Enterobacteriaceae and consists of at least 11 species, three of which clearly are human pathogens⁷³: *Yersinia pestis*, *Y. pseudotuberculosis* (both formerly included in the genus *Pasteurella*), and *Y. enterocolitica*. *Y. pestis*, the causative agent of plague, is found in rodents and insect vectors and is discussed in Chapter 112.

Y. enterocolitica and *Y. pseudotuberculosis* are responsible for a variety of syndromes, some of which originally were called *pseudotuberculosis*. Infections caused by these primarily enteropathogenic *Yersinia* spp. now are collectively referred to as *yersiniosis*, which is the focus of this chapter. Molecular phylogenetic analysis suggests that *Y. pestis* evolved from *Y. pseudotuberculosis* 1500 to 20,000 years ago.⁴ The genomes of representative strains of the three pathogenic *Yersinia* spp. have been sequenced.²¹⁰

During the past 4 decades, *Y. enterocolitica* has been recognized as an important human pathogen worldwide and is a common cause of gastroenteritis in some pediatric populations of the industrialized world.^{1,50,60,128} *Y. enterocolitica* also has drawn attention because of its immunologic or postinfectious manifestations, which include reactive arthritis and erythema nodosum.⁵⁰ *Y. pseudotuberculosis*, although widespread, is a much less common cause of human disease.⁷³ In Japan, it has been associated with clinical illness that sometimes has resembled Kawasaki disease.

HISTORICAL ASPECTS

In 1883, Malassez and Vignal¹⁴¹ described a bacterium that produced a disease they named *pseudotuberculosis*. The first case of mesenteric adenitis, the most common syndrome produced by *Y. pseudotuberculosis*, was reported in 1913 by Saisawa.¹⁸⁶ In 1954, Knapp and Masshoff⁶¹⁶ first reported the clinical features of infection produced by this organism.

The existence of a species of *Yersinia* other than that causing pseudotuberculosis was suggested in 1933 by Gilbert,⁶⁶ who reported an unusual infection in animals. In 1964, it was named *Y. enterocolitica* by Frederiksen.⁶³

The genus is named for A. J. Yersin, the French bacteriologist who first isolated the plague bacillus.²⁰⁰ During the past 50 years, an extensive literature detailing the microbiology, pathology, epidemiology, molecular pathogenesis, and clinical features of disease caused by *Y. pseudotuberculosis* and *Y. enterocolitica* has accumulated.*

*References 13, 23, 25, 26, 48, 50, 58, 88, 89, 94, 100, 114–117, 128, 136, 148, 183, 197, 199, 203, 216, 229.

MICROBIOLOGY

Yersinia organisms are large (0.5 to 1 $\mu\text{m} \times 1$ to 2 μm or larger), gram-negative, and ovoid or rod-shaped. *Y. enterocolitica* and *Y. pseudotuberculosis* are motile at 22° to 25°C (71.6°F–77°F) but not at 37°C (98.6°F). Similar to other members of Enterobacteriaceae, *Yersinia* organisms are facultative anaerobes and grow well on ordinary media. On Gram staining, *Y. pseudotuberculosis* appears as a large coccobacillus. Staining with methylene blue and carbol fuchsin discloses a bipolar (safety pin) morphology of most, but not all, strains. *Y. enterocolitica* is smaller and shows little, if any, bipolarity.^{197,200}

Unless careful biochemical and physiologic studies are conducted, *Yersinia* organisms may be confused with coliforms, such as *Morganella*, *Proteus*, *Shigella*, *Salmonella*, and *Providencia* spp., or *Escherichia coli* or with *Y. pestis* or *Brucella*, and *Achromobacter* organisms. *Yersinia* organisms reduce nitrates and are oxidase negative, catalase positive, and andurease positive. *Yersinia* organisms usually do not ferment lactose but produce α -galactosidase. All strains of *Y. pseudotuberculosis* and most strains of *Y. enterocolitica* isolated in Europe are indole negative. Most strains of *Y. enterocolitica* found in the United States have been indole positive.^{53,70,95,158,164,197,200}

Although these two species of *Yersinia* share many properties, they are distinguishable on the basis of several biochemical activities, antigenic structure, and sensitivity to various *Yersinia* phages.¹⁸⁵ *Y. enterocolitica* produces an acid slant and acid butt on triple sugar iron agar caused by fermentation of sucrose, whereas *Y. pseudotuberculosis* produces an alkaline slant and an acid butt. *Y. enterocolitica* elaborates ornithine decarboxylase and ferments sucrose and amygdalin. *Y. pseudotuberculosis* does none of these, but it ferments adonitol, which *Y. enterocolitica* does not.^{95,200}

Commercially available tests used to identify Enterobacteriaceae in clinical laboratories may not contain the biochemical reactions needed to identify specific *Yersinia* spp. Traditional macroscale biochemical testing may be required to distinguish *Y. enterocolitica* and *Y. pseudotuberculosis* from nonpathogenic *Yersinia* spp.^{80,132} On solid culture media, colonies of the pathogenic species typically are small, smooth, opaque colonies. The colonies of nonpathogenic species are larger and more translucent.¹⁰⁹ The emerging bacterial identification method, matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry, appears reliable for distinguishing *Yersinia* isolates at the species level.²⁰¹

Genomes and Typing of *Yersinia* Strains

Biotyping and serotyping have been the predominant methods used to characterize strains of *Y. enterocolitica*. At least 54 to 60 serotypes of *Y. enterocolitica* exist on the basis of variability of somatic O antigens, but only 11 typically are associated with human disease.^{23,25,60,73,213} Six biotypes of *Y. enterocolitica*, designated 1A, 1B, and 2 to 5, have been defined on the basis of phenotypic differences in 12 biochemical reactions.^{25,35,212}

Biotypes 1A, 2, 3, 4, and 5, now designated as *Y. enterocolitica* subsp. *paleartica*, are considered generally low pathogenic.¹⁹¹ Biotype 1B, now designated as *Y. enterocolitica* subsp. *enterocolitica*, is considered highly pathogenic. Further subspecies distinctions may be forthcoming.¹⁹² The genomes of biotypes 1A, 1B, and 2 to 5 are about 4.9, 4.6, and 4.5 Mb, respectively.¹⁷⁷ Genomic size differences are primarily related to number and distribution of insertion sequences.

Only a few serotype:biotype combinations are regarded as human pathogens: O:8, O:4, O:13a, 13b, O:18, O:20, and O:21 (biotype 1B); O:9 and O:5,27 (biotype 2); O:1,2,3 and O:5,27 (biotype 3); O:3 (biotype 4); and O:2,3 (biotype 5).²¹⁸ These pathogenic strains, which carry *Yersinia* virulence plasmids (pYV), generally have negative test results for pyrazinamidase activity, esculin hydrolysis, and salicin fermentation. Nonpathogenic strains, generally of biotype 1A, have positive test results for each of them.^{44,51,107} Data suggest that some biotype 1A strains that lack pYV and other *Yersinia* virulence factors also may cause gastroenteritis.^{72,191,193}

Strains of *Y. enterocolitica* can be typed genetically by multilocus sequence typing (MLST),¹⁹² repetitive element-based (interrepeat) polymerase chain reaction (PCR), pulsed-field gel electrophoresis,¹⁵³

and ribotyping.¹³³ An MLST scheme derived from whole-genome sequence data has recently been described⁷⁹ and likely will become a standard for epidemiologic investigations.

The complete genomes of the Old World biotype 3/O:9 strain 105.5R(r), prototypical of isolates common in Europe and Japan, and New World biotype 1B/O:8 strain 8081, prototypical of isolates in China, have been compared. The type III secretion systems differ, and strain 8081 has lost ancestral clusters of genes that contribute to enteric survival and pathogenesis.²²³ Other genomic studies have shown that low pathogenic *Y. enterocolitica* subsp. *paleartica* biotype 4/O:3, which causes sporadic human disease and commonly colonizes pigs worldwide, also possess a type III secretion system and other alternative virulence determinants in contrast to the high pathogenic *Y. enterocolitica* subsp. *enterocolitica* (biotype 2) strains associated with outbreaks of human disease in Northern Europe.¹⁶

At least 11 antigenic groups of *Y. pseudotuberculosis* exist on the basis of variation of somatic O antigens. They have been labeled 1a, 1b, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b, and 6.^{76,99,140} Type 2 is related antigenically to *Salmonella* group B, and type 4 is related to *Salmonella* groups D and H.⁷¹ Two clusters of *Y. pseudotuberculosis* have been described using MLST. Strains of one cluster are distributed worldwide and usually harbor pYV. The second cluster lacks pYV and is currently restricted to the Far East.⁴³

EPIDEMIOLOGY

Although most of the early reports of yersiniosis caused by *Y. pseudotuberculosis* and *Y. enterocolitica* came from northern Europe, these microbes have been identified with increasing frequency in all parts of the world.¹² *Y. enterocolitica* infections are more common in the United States than *Y. pseudotuberculosis*. Between 1996 and 2007, 1355 cases of foodborne *Y. enterocolitica* infections were identified by FoodNet in contrast to only 18 cases of foodborne *Y. pseudotuberculosis*.¹³⁵ The median ages of infected persons were 6 years (0 to 94 years) and 47 years (16 to 86 years), respectively.

During 1996 to 2009, FoodNet data show that the rate of foodborne disease caused by *Y. enterocolitica* in the United States was stable at 0.5 per 100,000 population.¹⁶¹ Rates have been highest in blacks, but declined from 3.9 to 0.4 per 100,000 during this time period. The rate in black children younger than 5 years declined from 41.5 to 3.9 per 100,000. The overall rate among blacks was lower than whites in 2013. Rates are highest in children younger than 10 years and adults 70 years and older. In 2013, the rates of *Y. enterocolitica* infection in children younger than 5 years and 5 to 9 years were 1.35 and 0.6 per 100,000 population. Cases were reported year-round with highest frequency in April followed by January and December.³⁶

Yersinia enterocolitica

Y. enterocolitica is distributed worldwide but is isolated most frequently in cooler climates.¹⁴⁹ Whether such geographic differences reflect differences in reservoirs or culinary practices that may enhance the risk for acquisition of this organism or instead represent differences in surveillance for the disease and use of more sensitive culturing techniques in these areas is unclear.⁵⁰ Increased frequency of infections during fall and winter has been reported from Europe¹⁸⁹ and the United States,¹ but no seasonality is evident among outbreaks of disease in which more than three cases of *Y. enterocolitica* disease have been identified.⁵⁰

Geographic differences in serotype distribution and frequency also exist. Sporadic infections caused by biotype 4/serotype O:3 and biotype 3/serotype O:9 strains are common in Europe,^{9,92} but outbreaks rarely have occurred.⁵⁰ In North America, multiple serotypes have been responsible for sporadic disease,^{18,24,35,69,189,195} but more recently serotype O:3 has become predominant.^{35,54,128} Outbreaks have been caused by serotype O:8 in the United States and by serotypes O:5 in Canada.⁵⁰ Disease caused by serotype O:8 has been reported in Europe.⁹² Biotype 2/serotype O:9 is predominant in China.²²³

The true incidence and prevalence of *Y. enterocolitica* infection are unknown.⁵⁰ The reported proportional frequency of isolation of *Y. enterocolitica* from stool cultures from patients with diarrhea has ranged

TABLE 113.1 Percentage of Stool Cultures Yielding *Yersinia enterocolitica*

Location	Years	Population	Total Cultures	Percentage <i>Y. enterocolitica</i>
Canada ¹⁴²	1977–78	Symptomatic children	6364	2.8
The Netherlands ⁹³	1982–84	Enteritis patients <40 y	827	2.9
Italy ¹⁴⁷	1981–85	Children with diarrhea	2500	1.4 ^a
New Zealand ⁶⁰	1988–93	Patients with gastroenteritis	231,128	0.6
Detroit, MI ⁵²	May–November 1977	Children with diarrhea	1262	0
New York state ¹⁸⁹	1976–80	Survey of cultures from a state laboratory, six hospitals, and several daycare centers	2487	0.9 ^b
US ^c (seven cities) ¹²⁸	November 1989–January 1990	All stool cultures submitted to seven hospitals	4841	0.8
St. Louis, MO ¹¹³	1998–2001	Children presenting to an emergency department with diarrhea	1626	0.1

^aYearly percentages during the 5 years ranged from 0% to 4.4%.

^bThis increased to 4% of 3035 isolates when cultures from an outbreak and other screenings were included.

^cIncludes Detroit, MI.

from 0% to 3.2% in series from Europe, the United States, and New Zealand (Table 113.1).^{52,60,92,128,142,147,189} Symptomatic infection occurs more commonly in children. Most series show a slight male predominance of approximately 1.3:1.^{54,60,142,212} Animals and water sources are the primary environmental reservoirs for *Y. enterocolitica*, but the biotypes and serotypes of the strains found in them usually differ from those causing human disease.^{35,50,189} Blood transfusions also may be a source of *Y. enterocolitica* infection.³⁷

Animal Reservoirs

Y. enterocolitica strains have been isolated from a wide variety of mammals (dogs, pigs, sheep, rabbits, guinea pigs, cows, horses, chinchillas, and monkeys), frogs, fish, flies, fleas, snails, crabs, and oysters. Birds do not seem to be a major reservoir for *Y. enterocolitica*, although avian isolates have been reported.^{50,95,136} The proportion of enteric illness attributable to animal contact in the United States in recent years is 1%.⁷⁸

Pigs seem to be an important reservoir for the human pathogenic serotypes O:3 and O:9 in Europe and Japan and serotype O:3 in North America and South Africa.^{50,128,171} The biochemical and phage typing profiles of isolates from pigs are similar to those of strains commonly responsible for human infections.²¹⁶ *Y. enterocolitica* has been isolated from the tongue, tonsils, and cecal contents of swine and from pork, ham, and butcher shop cutting boards.^{50,70} Pig farmers in Finland were 3 times and 2.4 times as likely to have seropositivity to serotypes O:3 and O:9, respectively, than were berry farmers.¹⁸⁸

Wild rodents captured in areas of Japan where human infections caused by *Y. enterocolitica* serotype O:8 had occurred were shown to harbor isolates of the same serotype.⁴⁶ Two distinct serotype O:8 strains, defined by restriction enzyme analysis of the virulence plasmids, were isolated from humans and rodents. This finding suggests that rodents are a potential source of sporadic human infection in Japan.

Apparent transmission to humans from dogs and cats also has been reported. A fecal–oral or oral–oral route has been postulated but not confirmed. Little evidence supports airborne or insect vector–borne transmission.⁵⁰

Foods and Water

In countries with high numbers of cases of yersiniosis, ingestion of raw pork has been common. Infection with serotypes O:3 and O:9 was highly associated with ingestion of raw pork during the 2 weeks preceding the illness in a case-control study.²⁰⁸ In Belgium, laboratory surveillance that began in 1967 showed yearly increases in cases through 1986. After a media campaign was launched to dissuade people from eating raw or undercooked pork or pork products and to educate consumers regarding good hygiene practices during food preparation, the number of isolations of *Y. enterocolitica* decreased from a high of 1469 in 1986 to 707 in 1996.²¹⁸ Eating raw minced pork or other foods prepared from raw pork products remains an ongoing risk factor for *Y. enterocolitica*

infection for young children.^{22,97,182} Preparation of chitterlings in the household was a risk factor for *Y. enterocolitica* infection in outbreaks among children in Michigan¹ and Illinois.³⁸

Ingestion of contaminated water has led to sporadic cases and outbreaks.^{50,57} Bean sprouts immersed in contaminated water and ingestion of tofu (bean curd) packed in untreated spring water led to outbreaks in Washington state in 1981 and 1982.²⁰⁶ However serotypes commonly found in water samples rarely are isolated from humans with symptomatic disease.³⁵

Contaminated milk has been implicated as the source of several large outbreaks of *Y. enterocolitica* infection.^{5,19,50,213} Whipped cream and ice cream may harbor the organism. Contamination of milk products after pasteurization has been documented. *Y. enterocolitica* has been found in raw milk samples from cows and goats. Samples of beef, lamb, poultry, oysters, and a variety of vegetables also have been found to be contaminated with *Y. enterocolitica*.^{32,50,70}

Serotypes O:3, O:4,33, O:5,27, O:7,8, O:8, O:10, O:13, and O:16 cause most human disease in North America but rarely are isolated in surveillance of water or food samples. Serotype O:8 strains have been cultured from cattle, milk, and water samples¹⁵⁸; serotype O:4,33 strains have been isolated from pigs and cattle; and serotype O:4,32 strains have been found in cheese, ham, sausage, raw beef, and one pancake specimen.^{35,189,213}

Outbreaks of *Y. enterocolitica* disease have involved communities, families (with interfamily spread), hospitals, and schools.^{14,18,37,75,142,213,231} The sources of the organism have been various foods and animals, especially dogs, as noted earlier. Yersiniosis also resembles disease caused by *Salmonella* and *Shigella* organisms in many respects, including the environmental sources of the organisms, the clinical syndromes, and the occurrence of asymptomatic infection.

Incubation, Carriage, and Transmission in Humans

The incubation period of *Y. enterocolitica* enterocolitis ranges from 1 to 14 days, with a median of approximately 4 days.^{35,50,128} The minimal infective dose of *Y. enterocolitica* is unknown. Ingestion of 3.5×10^9 organisms by a volunteer resulted in diarrhea in less than 1 day, but such large inocula are unlikely to be encountered clinically. The duration of excretion of the organism after development of infection in children ranges from 14 to 97 days (mean, 42 days).¹⁴² The impact, if any, of antibiotic treatment on the duration of carriage is unknown.

Transmission to household members occurs uncommonly, even among young children, who are at higher risk for development of symptomatic disease.^{19,142,206} Six percent of household contacts developed disease in one outbreak,²⁰⁶ but several large outbreaks with no secondary household cases have been reported.⁵⁰

Nosocomial transmissions have been documented. A young child who was hospitalized in Finland with acute gastroenteritis was the source case of infection in a housekeeping worker and four nurses who cared

for her.²¹¹ Person-to-person contact was considered the likely mode of transmission in a hospital outbreak that involved nine patients in Canada.¹⁷⁴

Yersinia Enterocolitica and Blood Transfusion–Related Sepsis

In this era of screening for viral infections in blood donations, bacterial sepsis has become the most frequent infectious complication of blood transfusions in developed countries. Sporadic cases of *Y. enterocolitica* sepsis related to contamination of transfusions of red blood cells (RBCs) have been recognized since 1987 and have occurred in the United States, Europe, and Australia.^{37,74} *Y. enterocolitica* is the most common cause of transfusion-related sepsis.¹⁰⁵ Rapid-onset septic shock, fever, chills, and atypical signs such as explosive diarrhea are common. Case fatality is about 50%.^{45,74}

In many cases of transfusion-related sepsis, the contaminated RBC units had been stored for 25 days or more.⁸⁷ After experimental inoculation of small numbers of *Y. enterocolitica* into packed cells kept at 4°C (39.2°F), the organisms continue to replicate, reaching concentrations of 100 colony-forming units (CFU)/mL in 7 days and 10⁶ CFU/mL in 21 days. This lag of 1 to 3 weeks in rapid growth is consistent with the increasing iron stores released from hemolyzing RBCs during storage. *Y. enterocolitica* multiplication is supported by glucose and adenine, which are part of RBC anticoagulant and additive solutions. Although growth is calcium-dependent during human infection at body temperatures, *Y. enterocolitica* can replicate in calcium-free media (e.g., RBCs anticoagulated via citrate chelation) at temperatures less than 30°C (86°F).⁷⁴ High levels of endotoxin can result from bacterial replication in RBC products and have been documented in samples from RBC units that led to transfusion-related sepsis.⁴⁵ Timely administration of effective antimicrobial agents appears to improve outcomes, suggesting a significant contribution from viable microbes.⁷⁴

Prevention of Disease

During outbreaks, efforts should be made to identify environmental sources and vehicles of transmission.⁵⁰ A single environmental source can harbor multiple serotypes of *Y. enterocolitica*, such that resulting outbreaks may be polyclonal.²⁰⁶ Enteric precautions should be used for hospitalized patients with diarrhea caused by *Y. enterocolitica* (as with other causes of gastroenteritis).⁵⁰ At the population level, decreased consumption of raw or undercooked pork products potentially can reduce the incidence of infection.^{208,218}

Yersinia pseudotuberculosis

Y. pseudotuberculosis may infect individuals of all ages, but at least 75% of patients with clinically apparent disease are children younger than 15 years.^{99,185} Infection in young infants has been reported.^{99,225} Of 130 cases diagnosed in Great Britain from 1959 to 1970, boys were involved three times more frequently than girls.¹³⁶ Infections occur more commonly during the cold months of the year.^{99,184} The seasonal winter peak of human infection produced by *Y. pseudotuberculosis* is similar to that seen in wild and domesticated animals.^{114,115,185}

The attack rates for children living in rural and urban areas seem to be the same. *Y. pseudotuberculosis* occasionally has been recovered from healthy individuals. Exposure to the organism seems to be uncommon; antibody to *Y. pseudotuberculosis* was detected in only one of 2000 sera samples from individuals with no history of yersiniosis.^{63,185}

Y. pseudotuberculosis is distributed worldwide in a large variety of animals and birds, but infection seldom occurs.⁶⁷ Guinea pigs, rodents, and rabbits are infected most often¹³⁶ and may experience a plague-like illness.^{67,95} Lesions in guinea pigs may be confused easily with lesions caused by *Y. pestis*. Rats and other rodents also may have plague-like disease caused by *Y. pseudotuberculosis*. The microbe can be cultured from tongue, tonsils, intestines, and large organs of infected animals.¹⁵⁷

Infection has been reported in various domestic animals (cattle, sheep, goats, cats, dogs, hamsters), commercially raised fur bearers (chinchillas, mink, coypu), and other wild or captive animals (rabbits, raccoons, foxes, deer, beavers, monkeys, puma, kangaroos). *Y. pseudotuberculosis* has been found in more than 50 species of birds,^{82,108,136} and epizootics have occurred among turkeys, ducks, pigeons, and doves and in aviaries of canaries and finches. Strains obtained from animals and

birds in the United States are predominantly of serotypes 1a, 1b, and 3.^{136,185}

The incubation period for human disease ranges from 41 hours to 20 days.⁹⁹ In a food-associated outbreak in Finland, the median incubation period was 8 days (Fig. 113.1).¹⁰² The organism can survive in fresh tap water for 46 days at room temperature and for 8 months at 4°C (39.2°F). It can survive at 4°C in meat for 145 days and in milk and bread for 2 to 3 weeks.¹³⁶

A family outbreak of mesenteric adenitis caused by *Y. pseudotuberculosis* that involved four siblings aged 7 to 14 years has been reported.¹⁷³ A pet dog was shown to have increasing antibody titers at the time the children were ill.

Periodic outbreaks have been reported in Japan, northern Europe, and areas of the former Soviet Union. Sandwiches prepared by a single bakery were the primary risk factor for 67 cases that occurred in a 3-week period in Japan.⁹⁹ Drinking unchlorinated well water or mountain stream water has been the source of other outbreaks. Children were much more likely to have clinical disease than adults. More recent outbreaks in Finland have been associated with contaminated lettuce and grated carrots.¹⁰²

PATHOLOGY

The diseases produced by *Y. enterocolitica* and *Y. pseudotuberculosis* are similar and share the histopathologic theme of involvement of the lymphoid tissues of the intestinal mucosa and mesentery.

Yersinia enterocolitica

Y. enterocolitica infection predominantly affects the gastrointestinal tract. The most severe clinical symptoms correlate with an acute terminal ileitis. The mucosal surface of the ileum and other involved sites may be inflamed diffusely. Ulcerations may occur throughout the gastrointestinal tract and may be small and superficial or extend to the muscularis propria. Mucosal and submucosal hyperplasia of Peyer's patches occurs with scattered microabscess formation.

Ulcers occur primarily over the sites of lymphoid tissue within the mucosa, which accounts for their more longitudinal appearance in the small intestine and an oval or punctate appearance in the stomach and colon. Ulcerations are characterized by necrosis of the epithelial layer. In the colon, the necrosis also may extend through the superficial third of the crypts. Large colonic ulcerations covered by pseudomembranes or mucoid debris are seen occasionally. Ulcerations may progress to perforation, with subsequent development of peritonitis or gastrointestinal hemorrhage in severe cases.^{29,68,216,217}

The inflammatory response in the mucosa consists mainly of neutrophils and mononuclear cells. Lymphocytes and plasma cells also may be seen. Giant cells are not seen, although a granulomatous appearance can be imparted by the presence of plump epithelioid histiocytes. Numerous colonies of gram-negative bacteria often can be seen beneath the mucosal ulcerations and within the microabscesses that occur in the lymphoid tissues.^{68,216,217}

The appendix usually appears normal on gross inspection, but small focal ulcerations frequently are present.⁷ Large areas of necrosis are found occasionally, and acute, suppurative appendicitis has been reported.^{29,104,142} Periappendicular inflammation may result from a true appendicitis or an adjacent terminal ileitis.²¹⁶

Mesenteric adenitis, the hallmark of infection caused by *Y. pseudotuberculosis*, also is a common feature of enterocolitis caused by *Y. enterocolitica*. The lymph nodes usually show numerous large pyroninophilic cells and mitotic figures in the cortical area and marginal sinuses. Small collections of leukocytes in the germinal centers are seen in some cases and suggest formation of microabscesses. In severe cases, extensive areas of necrosis circumscribed by a neutrophilic infiltrate may be seen. The sinusoids can become filled with neutrophils and mononuclear cells. The germinal centers often appear reactive.

The histopathologic appearance of the mesenteric adenitis of infection caused by *Y. enterocolitica* can resemble the adenitides caused by cat-scratch disease (*Bartonella henselae*), toxoplasmosis, infectious mononucleosis, and *Y. pseudotuberculosis*.^{7,216,228} The necrotizing epithelioid granulomata that may be present in mesenteric adenitis caused by *Y.*

FIG. 113.1 Distribution of incubation periods for *Yersinia pseudotuberculosis* infection to onset of gastrointestinal (GI) symptoms and erythema nodosum after point source exposure to contaminated carrots. Of 72 case patients with a known date of onset, 51 had GI symptoms and 38 had erythema nodosum only; 28 had GI symptoms and erythema nodosum and appear twice in the graph. (From Jalava K, Hakkinen M, Valkonen M, et al. An outbreak of gastrointestinal illness and erythema nodosum from grated carrots contaminated with *Yersinia pseudotuberculosis*. *J Infect Dis*. 2006;194:1209–16.)

pseudotuberculosis have not been described in infection caused by *Y. enterocolitica*. A more recent study of six cases suggests that biotype 1B strains may be more likely to cause suppurative inflammation, whereas biotype 2 through 5 strains may be more likely to cause granulomatous infection.¹²⁵

Yersinia pseudotuberculosis

Numerous reports collectively have described the pathology of infection caused by *Y. pseudotuberculosis*.^{53,61,94,115,137,143,144,148,173,224} Grossly enlarged, soft, and inflamed mesenteric lymph nodes are the predominant finding on laparotomy. They frequently are located at the ileocecal angle. Punctate hemorrhages and small, yellow microabscesses may be present on the surfaces of the nodes at the height of infection. The appendix usually appears normal, but the terminal ileum and cecum occasionally appear inflamed. A necrotic purulent mass sometimes is seen in the mesentery.

Histopathologic findings in the mesenteric lymph nodes include enlarged follicles and small abscesses; hyperplasia of reticulum cells; necrosis of the nodes with infiltrates of neutrophilic leukocytes and plasma cells; and, in some instances, punctate hemorrhages. Scattered clusters of neutrophils may be seen within the sinusoids and germinal centers without formation of abscess or necrosis. Atypical mononuclear cells, some of which may be mitotic, may be present in the sinusoids. When necrosis is absent, large numbers of eosinophilic leukocytes

occasionally are seen surrounding reticulogranulocytic infiltrates in the nodes. Giant cells can occur and may cause the histologic picture to be confused with that of tuberculosis.

The mesenteric adenitis produced by *Y. pseudotuberculosis* seems to progress through histopathologic stages akin to those of other pyogenic infections that can lead to formation of abscesses.^{53,76} Reticulogranulocytic infiltration is followed by formation of an abscess, with subsequent organization and clearing of the abscess. The inflammatory process of *Y. pseudotuberculosis* seems to remain confined to the lymph nodes without rupture through the nodal capsule.

Focal mucosal ulcerations may be seen in the ileum, and are more likely to be found at the site of Peyer's patches. Aggregates of neutrophilic leukocytes similar to those in mesenteric nodes may be seen in germinal centers within mucosal lymphoid tissue. Fibrinoid material may be a prominent feature at these sites. Small areas of necrosis surrounded by reticulum cells and leukocytes also may be present in the submucosal follicles.^{61,115,117,224} Ulcerated lymphoid follicles in the intestinal wall are connected to the regional lymph nodes by a lymphangitis. This anatomic situation is analogous to the primary complex of tuberculosis.

Despite a clinical picture of acute appendicitis as the presenting feature of infection by *Y. pseudotuberculosis*, the appendix typically is grossly and microscopically normal. Inflammatory changes, when present, usually are in the form of a periappendicitis. Phlegmonous appendicitis can result from infection caused by *Y. pseudotuberculosis* but is rare.^{53,91}

PATHOGENESIS

The pathogenesis of infection by the two enteropathogenic *Yersinia* spp. has been studied extensively. After ingestion and successful transit to the small intestine have occurred, these *Yersinia* spp. are able to penetrate into the lamina propria primarily by passing through the cytoplasm of M cells that reside on the mucosal surface of Peyer's patches. The bacteria are internalized in membrane-bound vacuoles in which they survive but do not replicate. After reaching the lamina propria, the microbes multiply as extracellular microcolonies in lymph follicles and Peyer's patches, where they may reach densities of 10^9 CFU/g of tissue.⁵⁶

Neutrophils and macrophages infiltrate these sites in response to the infection, ultimately creating microabscesses, but *Y. enterocolitica* is able to resist phagocytosis and intracellular killing by neutrophils and macrophages. *Yersinia* spp. also inhibit production of tumor necrosis factor- α (TNF- α) and interferon- γ (IFN- γ) and induce apoptosis in host macrophages. The microbes disseminate to the mesenteric lymph nodes, apparently through lymphatic vessels. Infection usually is contained at this point, although abscesses often develop within the nodes. Systemic spread occurs occasionally, more commonly with infection by serotype O:8 strains.

Control of infection caused by *Y. enterocolitica* is the result of T-cell responses that lead to restriction of bacterial growth in infected organs through stimulation of production of *Yersinia*-specific antibody by B cells and cytokine-mediated activation of macrophages. These responses ultimately overcome the antiphagocyte strategies of *Yersinia*. Production of TNF- α and IFN- γ seems to be an essential part of the host response to *Yersinia* infections. *Yersinia* microbes generally do not survive within granulocytes after they have been successfully phagocytosed.^{46,48,49,162}

Only a few of the many serotypes of *Yersinia* spp. are capable of infecting humans. Numerous virulence factors have been identified among these "pathogenic" strains (Table 113.2). Most of them are encoded on the *Yersinia* virulence plasmid pYV. At least eight chromosomal loci that encode novel *Yersinia* virulence factors have been found by tagged mutagenesis studies.⁶⁶ Much of this knowledge has been gained through mouse and rabbit models of human infection and observations of interactions of *Yersinia* organisms with in vitro cell culture models.^{28,46,90,138,169}

The distinctions in pathogenesis between the two enteropathogenic *Yersinia* spp. and *Y. pestis* seem to be caused partly by the presence in *Y. pestis* of (1) two additional plasmids that encode a plasmin activator and a mouse exotoxin and (2) a hemin storage locus on its chromosome.

TABLE 113.2 Known and Putative *Yersinia* Virulence Factors^a

Stage of Pathogenesis	Determinant	Genomic Origin ^b	Function	Conditions of Expression
Gastric transit	Urease	Chromosome	Aids survival of gastric acidity	
Mucosal invasion	Invasin (inv)	Chromosome	Attachment, invasion via β_1 integrins; broad host/cell range	28°C
	Attachment invasion locus (AiL)	Chromosome	Attachment, lesser invasion factor; more host-specific than invasion; serum resistance	37°C
	<i>Yersinia</i> adhesin A (YadA)	Plasmid	Attachment, invasion; reduces opsonization by C3b by binding complement factor H; ? role in resistance to antibacterial polypeptides (e.g., bactericidal permeability-increasing protein)	37°C and any calcium concentration
Disruption of phagocyte function	Effector proteins (act on host cells)	Plasmid		37°C and low calcium concentration
	YopH		Tyrosine phosphorylase that prevents phagocytosis by macrophages by preventing assembly of focal adhesion structures of phagocytes	
	YopE		Phagocytosis resistance via induction of host cell actin filament rearrangements	
	YopJ/P		Cysteine protease/acetyltransferase that inhibits mitogen-activated protein kinase and nuclear factor κ B signaling via interruption of posttranslational covalent additions of ubiquitin-like molecules to these enzymes; this prevents production of cytokines (tumor necrosis factor- α), inhibits the host immune response, and triggers apoptosis of macrophages.	
	YpkA/YopO		Inhibits kinase phosphorylation via an acetyltransferase function	
	YopT		Serine kinase, causes rounding up of cells, specific target unknown	
	YopM		Disruption of actin filaments	
			Role unclear	
			Inhibits thrombin-induced platelet activation in vitro but is delivered intracellularly during infection	
			Leads to depletion of natural killer cells and alters expression of IL-15 and IL-15 receptors	
	Membrane attachment, pore insertion into host cell	Plasmid		37°C and low calcium concentration
	YopB and YopD		Pore formation in host cell membrane to allow translocation of effector proteins into the host cell	
	YopQ (YopK)		Suppression of IL-8 secretion by epithelial cells	
			Controls translocation via modulating the size of the YopB, YopD pore in the host cell membrane	
	YopN		Involved in control of translocation, perhaps stabilizing contact between the bacterium and host cell membranes	

TABLE 113.2 Known and Putative *Yersinia* Virulence Factors—cont'd

Stage of Pathogenesis	Determinant	Genomic Origin ^b	Function	Conditions of Expression
	LcrV ^a		Assists extrusion of YopB and YopD to the host cell membrane Homologue of the <i>Y. pestis</i> V antigen Antibodies against V antigen seem to be protective at the serotype level	
	Yop secretion apparatus (Ysc) (28 proteins in total; part of microbe) YscD, YscR, YscU, and LcrD/YscV YscC secretin	Plasmid	Form a complex that spans the inner bacterial membrane (gated pore/channel) Forms a pore in the outer bacterial membrane that may connect with the inner membrane pore ATPase that energizes Yop transfer across the membranes	37°C and low calcium concentration
	YscN LcrQ (in <i>Y. pseudotuberculosis</i>), YscM1 and YscM2 (in <i>Y. enterocolitica</i>)		Negative <i>yop</i> gene regulators that, when secreted, decrease in concentration in the bacterium, allowing <i>yop</i> expression	
	Cytosolic chaperones (Syc) (6 proteins in total; within microbe)	Plasmid	Secretion/translocation pilots or antidegradation roles for effector proteins	37°C and low calcium concentration
Colonization of Peyer's patches and lymph nodes	<i>Yersinia</i> phospholipase A	Plasmid	Serum resistance, inhibition of phagocytosis	37°C and low calcium concentration
Iron metabolism	Yersiniabactin	Chromosome (high pathogenicity island)	Siderophore	37°C, iron starvation
Diarrhea	<i>Yersinia</i> heat-stable enterotoxin (Yst)	Chromosome	Fluid secretion in intestine Precise role in pathogenesis of disease in humans is unclear, but found in clinical isolates from children with diarrhea	28°C (in vitro)
Systemic invasion	O antigen	Chromosome	Component of lipopolysaccharide Complement/serum resistance	

IL, Interleukin; Lcr, low calcium response; Yop, *Yersinia* outer membrane protein (although not all such designated proteins reside in the outer membrane).

^aThe complete pathogenesis/virulence roles of several gene products encoded on the *Yersinia* virulence plasmid pYV and chromosomal sites have yet to be determined.

^bPlasmid refers to the *Yersinia* virulence plasmid pYV.

Data from references 25, 47, 48, 71, 75, 111, 121, 129, 151, 152, 162, 180, 187, 193, 194, 232, 233.

These additional factors may enable *Y. pestis* to survive in and transmit between fleas and rodents. Such transmission does not occur with the enteropathogenic *Yersinia* spp.¹⁸⁰

Bacterial Determinants of Mucosal Invasion

Two outer-membrane proteins encoded by chromosomal genes permit entry into various mammalian cell types in vitro and are likely to be responsible for the ability of *Yersinia* to invade into and through the intestinal mucosal epithelium. They have been named *invasin* and the *attachment invasin locus protein* (Ail). All isolates of *Y. enterocolitica* that are virulent in humans contain DNA sequences that encode for *invasin* and Ail. Nonpathogenic strains do not contain the genetic code for Ail, but most contain *invasin* genes that cannot be expressed because of chromosomal rearrangements. These proteins apparently are unique to the genus *Yersinia*.^{100,146,166}

Invasin attaches to receptors in the β_1 integrin family and induces an actin-mediated endocytosis of the microbe. It binds to β_1 -chain integrin receptors with approximately 100-fold higher affinity than do natural ligands, such as fibronectin. Such high-affinity binding triggers endocytosis-like internalization that involves clathrin.⁴⁹ *Invasin* is expressed maximally at ambient temperatures when the organism is in stationary phase. *Y. enterocolitica* microbes living in the environment probably exist in a stationary phase-like state and may be primed maximally for invasion of the host after ingestion. *Invasin* expression also can remain elevated at 37°C (98.6°F) when the pH is 5.5, and such conditions are encountered during passage through the intestinal tract. Ail is expressed maximally at 37°C, functions as an adhesin and an

invasion factor, and plays a role in the resistance of *Y. enterocolitica* to the bactericidal activity of human serum.^{100,101,166}

High levels of β_1 -chain integrin receptors are found on the luminal surface of M cells, which are antigen-sampling epithelial cells found in highest numbers overlying Peyer's patches in the intestinal tract.⁸³ Flagellum-dependent motility seems to be required for *invasin*-mediated invasion of cells by *Y. enterocolitica*.²³⁰

The following determinants are primarily relevant to *Y. enterocolitica*, although *Y. pseudotuberculosis* shares many of these features.

Yersinia Adhesin A

Yersinia adhesin A (YadA) is a multifunctional virulence factor of *Y. enterocolitica*. YadA is approximately 50 kDa and probably forms tetrameric fibrillae on the microbial surface. Its gene resides on the pYV plasmid and is transcribed at 37°C independently of the calcium concentration. YadA binds to extracellular matrix proteins, such as collagen, and mediates adhesion to cells. It may play a role in translocation of Yop effector proteins into eukaryotic phagocytic cells. YadA also inhibits the terminal complement attack complex, reduces opsonization by C3b through binding of complement factor H, and contributes to the ability of *Y. enterocolitica* to resist killing by antimicrobial polypeptides of human granulocytes. YadA knockout mutants are far less virulent in mice than is the parent wild-type strain.^{48,89,221}

Virulence Plasmid and Type III Secretion System

Pathogenic strains of *Y. enterocolitica* harbor a plasmid that consists of approximately 70 kb (denoted pYV) and encodes the low-calcium

response system of *Yersinia* spp., which involves a complex response to environmental conditions of 37°C and calcium concentrations of less than 2.5 mM, both of which describe the intracellular compartment of mammalian cells.^{48,194} Plasmid-encoded factors are required for survival and extracellular multiplication after reaching Peyer's patches. Plasmid-cured derivatives are ingested rapidly and killed by neutrophils in Peyer's patches, whereas wild-type strains are able to proliferate and spread through the lamina propria to adjacent villi. Plasmid-encoded factors are not required for *Y. enterocolitica* to penetrate the intestinal mucosa.⁸⁹

In DNA cross-hybridization studies, the pYVs of *Y. enterocolitica* serogroups O:9, O:3, and O:5 show 90% nucleotide identity with one another, 75% identity with the pYV of serogroup O:8, and 55% identity with the pYV of *Y. pestis* and *Y. pseudotuberculosis*. Despite the nucleotide divergence among the pYVs of the three *Yersinia* spp., the overall structures and most of the genes are highly similar among them. The *Yersinia* low calcium response plasmids are nonconjugative.^{48,194}

The *Y. enterocolitica* pYV contains approximately 70 genes, of which around 53 have protein products with known or putative functions (many of these are listed among the virulence factors in Table 113.2). pYV encodes *Yersinia* adhesin A and a system of six effector proteins that are delivered into host cells (primarily phagocytic granulocytes) through a complex mechanism of regulatory proteins, secretion chaperones, and proteins that act as secretion channels or pores in the bacterial and host cell membranes. This system, called a type III secretion system, denotes secretion of the bacterial proteins only in response to contact with a mammalian cell. The effector proteins and several others involving pore formation are designated Yops (*Yersinia* outer-membrane proteins), although most of them do not reside in the outer membrane. Similar type III secretion systems are found in other *Enterobacteriaceae*.^{48,194}

The secretion system is composed partially of syringe-like organelles—called *Ysc injectisomes*—that develop when *Yersinia* organisms are incubated at mammalian body temperatures. These injectisomes are protein pumps that span the peptidoglycan layer and the two bacterial cell membranes, topped by a needle-like structure protruding outside the bacterium. Twenty-seven proteins are involved in the structure; 10 of them are located internally and form a structure similar to the basal body of a flagellum, which also includes an ATPase that functions as a proton pump. A homomultimeric ring-shaped structure extends through the outer membrane, with a central pore diameter of about 50 Å.³³

As the injectisomes assemble, stocks of intracellular Yops are synthesized. Active transcription of *Yop* genes is limited to bacteria in close contact with eukaryotic cells. The secretion channel of the injectisome remains closed, with negative feedback mechanisms to prevent overproduction of Yops. On close contact with a phagocyte, the injectisome channels open, and secretion of effector Yops into the target cell begins.³³ This is accomplished through insertion of YopB and YopD into the host cell membrane, where these form a multimeric complex that serves as a pore for effector injection.¹⁵¹

After secretion into a phagocytic cell occurs, YopH, YopE, YopT, and YopO/YpkA disrupt its cytoskeletal dynamics, blocking phagocytosis (see Table 113.2). YopT is a cysteine protease that cleaves and inactivates Rho proteins, which are small membrane-associated GTPases that control the host cell actin cytoskeleton.¹⁸⁷ Other Yops inhibit production of TNF- α , interleukin-8 (IL-8), and other inflammatory chemokines and induce apoptosis of macrophages.³³

A similar type III secretion system is present in *Y. pseudotuberculosis*, which is considered to be primarily an extracellular pathogen.²³³ *Y. pseudotuberculosis* can survive within macrophages, and mouse studies suggest a small minority of invading microbes may reside intracellularly in multiple tissue sites. This system is able to transport Yops from phagosomes in macrophages into the cytosol and to inject Yops into mouse dendritic cells. YopJ inhibits dendritic cell-mediated T-cell responses via induction of apoptosis and reduction of surface molecule expression.²⁰⁷

Summary of *Yersinia* Pathogenesis

Pathogenic strains of *Y. enterocolitica* require calcium concentrations equivalent to those of serum and extracellular fluids in humans for

growth at body temperature. Plasmid proteins are synthesized maximally; however at 37°C and under conditions of low calcium concentrations, such as those found intracellularly. These regulatory effects of environmental calcium concentrations permit free growth of *Yersinia* organisms during extracellular life and production of factors that inhibit phagocytosis by macrophages and neutrophils when *Yersinia* organisms pass through the intracellular compartment during mucosal invasion or come into contact with these granulocytes.^{46,48,89}

A model of how pathogenic *Yersinia* organisms living in cold ($\leq 28^{\circ}\text{C}$ [$\leq 82.4^{\circ}\text{F}$]) environmental reservoirs are able to establish infection in the mammalian host can be described at the molecular level (see Table 113.2). *Yersinia* microbes living in the environment express invasin, which renders them ready to attach and invade the intestinal mucosal M cells after ingestion. Expression of invasin continues at body temperature during gastric passage to the intestines. Survival of gastric acidity is assisted by a urease-producing system.

During intracellular passage through M cells in the small intestine, pYV genes are likely to be activated (conditions of low calcium, 37°C). YadA can be produced at body temperature and may assist in mucosal invasion. Transcytosis from the intestinal lumen to the lamina propria seems to occur by a clathrin-mediated process that probably is a normal function of the host cell, after internalization is triggered. Ail also is synthesized after ingestion occurs and probably promotes attachment to migrating cells in the lamina propria that may facilitate extracellular spread of the microbes to regional lymph nodes and perhaps the liver and spleen.

To survive this journey, *Yersinia* organisms must evade phagocytosis by macrophages and neutrophils. YadA can inhibit complement opsonization, reducing the likelihood that phagocytosis will occur. When contact between the microbe and a host granulocyte occurs, the previously activated type III secretion system (described earlier) encoded by the pYV plasmid comes into play. A contiguous pore is inserted into the granulocyte cell membrane (involving YopB, YopD, YopQ, YopN, and LcrV). Effector proteins (YopE, YopH, YopJ/P, YopO/A, YopM, and YopT) then are translocated into the granulocyte cytoplasm, disrupting its abilities to ingest the bacterium and produce cytokines and triggering apoptotic cell death (see Table 113.2). Although this system of virulence factors is robust enough to facilitate short-lived infection that often causes mild to moderate clinical symptoms, the microbes that do not succumb to the innate immune response ultimately are contained and then eliminated by the adaptive host response.

Y. pseudotuberculosis, which does not express Ail or invasin, is able to penetrate the intestinal epithelial barrier through a cascade of steps initiated via binding to Toll-like receptor 2 on monocytes. This involves caspase 1 and IL-1 β production that ultimately leads to myosin light chain kinase activation in intestinal epithelial cells that disrupts tight junctions between them.¹⁰⁶

Iron Metabolism and Virulence

Iron is an essential growth factor for most bacteria, many of which release siderophores (high-affinity chelators) that bind ferric iron and then are taken up again through receptors by the microbe. *Y. enterocolitica* serotype O:8 and other biotype 1B strains synthesize a chromosomally encoded siderophore, designated *yersiniabactin*, which sits on the outer membrane of the bacterium. The presence of this siderophore decreases the concentration of environmental iron required for optimal growth and probably accounts for the increased virulence observed for serotype O:8 strains.^{50,89} The gene encoding yersiniabactin and the genes required for its biosynthesis, transport, and regulation compose the core of what is termed a *high-pathogenicity island* because of the high lethality for mice that its presence confers.¹⁷²

Serotypes O:8, O:4, O:13, O:18, O:20, and O:21 (all biotype 1B and historically considered American strains) are highly lethal to mice after intraperitoneal injection and are able to evoke a keratoconjunctivitis after inoculation into the conjunctival sac of guinea pigs (the positive Sereny test result). Oral infection in mice predominantly produces the features of mesenteric adenitis and systemic infection, rather than simple gastroenteritis, which is characteristic of human infection by American strains. The European serotypes, O:3, O:9, and O:5,27, yield a negative Sereny test result and cause mild diarrhea but not death in mice. The

^cMaculopapular rash or urticaria.

European serotypes of *Y. enterocolitica* do not produce yersiniabactin but are able to use siderophores synthesized by other organisms.^{46,89,146}

Deferoxamine, a *Streptomyces*-derived siderophore used clinically to treat iron overload states, can be used by *Y. enterocolitica* strains as a source of iron. The increased availability of ferric iron that exists in iron overload states—for example, hemochromatosis and diseases such as thalassemia, which require frequent red blood cell transfusions—also facilitates survival and growth of *Y. enterocolitica*. Iron overloading and deferoxamine are independent risk factors for development of systemic disease after intestinal infection with *Y. enterocolitica*.⁵⁰

Enterotoxin Production

All enteropathogenic strains of *Y. enterocolitica* produce a heat-stable enterotoxin that closely resembles the heat-stable toxin of *E. coli*. Both enterotoxins induce increases in levels of cyclic guanosine monophosphate levels in intestinal epithelial cells. The *Y. enterocolitica* enterotoxin is not plasmid encoded, and its presence does not correlate with the expression of other virulence phenotypes.⁶⁷ Because the enterotoxin is not produced in vitro at temperatures exceeding 30°C (86°F), production in the gastrointestinal tract and a causative role in diarrhea were thought to be unlikely.⁵⁰ Observations in the young rabbit oral infection model have shown, however, that enterotoxin-negative mutants did not induce diarrhea and the wild-type strain did. Clinical biotype 1A isolates from children with diarrhea in India produce *Y. enterocolitica* stable toxin-b. These findings suggest that *Yersinia* enterotoxins may play a role in causing the diarrhea frequently associated with *Y. enterocolitica* infection in children.^{89,164,193}

Gastric Acidity as a Protective Host Factor

Although *Y. enterocolitica* is able to grow under conditions at pH 5.0 to 9.0, optimal growth occurs at pH 7.0 to 8.0. Gastric acidity may play a protective role against some *Yersinia* inocula, although pathogenic *Yersinia* organisms produce a urease enzyme that facilitates survival. Therapeutic agents or clinical conditions that result in reduced gastric acidity may predispose patients to development of infection. *Y. enterocolitica* bacteremia has been reported after gastrectomy.^{50,121}

CLINICAL MANIFESTATIONS

Clinical disease caused by *Y. enterocolitica* occurs far more frequently than that caused by *Y. pseudotuberculosis*.^{60,131,130} Historically diarrheal illness has been considered the hallmark of *Y. enterocolitica* and the pseudoappendicular syndrome of mesenteric adenitis indicative of *Y. pseudotuberculosis*. Each species can cause enterocolitis and mesenteric adenitis, however. Various other clinical infections and postinfection syndromes also are caused by these microbes. In a series of patients

presenting with acute abdominal pain suggestive of appendicitis, the incidence of serologic evidence of *Yersinia* infection has ranged from 7% to 31%.¹⁵

Yersinia enterocolitica

The clinical features of the disease caused by *Y. enterocolitica*, primarily an acute enteritis, have been described by many investigators.* The clinical manifestations depend partly on the age and physiologic condition of the host.^{50,142,173} Enterocolitis is the most common presentation and occurs most often in young children. The pseudoappendicular syndrome, which results primarily from mesenteric adenitis and mimics acute appendicitis, occurs more commonly in older children and young adults.^{19,50,93,104,159,179} Asymptomatic infection can occur, but the relative frequency in contrast to symptomatic disease is unknown. The predominant clinical features of *Y. enterocolitica* infection in children are summarized in Table 113.3. Disease manifestations may be strain-related in some cases. The so-called pathogenic strains of biotype 1B are more likely to cause fever, whereas those of so-called nonpathogenic strains of biotype 1A may cause more vomiting.⁹⁷

Enterocolitis

Y. enterocolitica enterocolitis is characterized by diarrhea and abdominal pain. The diarrhea usually persists for 7 to 14 days.^{128,142,216} A range of 1 to 46 days of diarrhea has been reported.¹⁰⁹ Ten percent of cases may persist for 30 days or more,¹⁴² and chronic diarrhea persisting for several months has been described.⁵⁴

During the first week of symptoms, patients commonly have three to 10 stools per day, with a gradual decrease in frequency thereafter. Stools typically are greenish, exhibit variable consistency (usually watery or mucoid), and are not remarkably malodorous. Gross blood is noted in approximately 25% to 50% of patients. Vomiting occurs in 40% of cases. Nausea is a common symptom. The abdominal pain can be colicky, diffuse, or localized to the right lower quadrant or epigastrium. Fever occurs commonly and usually is of low grade, but may exceed 40°C (104°F); it usually resolves within 1 week.^{1,139}

Most cases are self-limited, but some children require hospitalization. Among 60 children hospitalized in Michigan between 1990 and 1997, the mean number of hospital days required was 4 (range, 1 to 17 days).¹

Fecal leukocytes are present commonly but not universally. The peripheral white blood cell count may range from 5600/mm³ to more than 30,000/mm³. Most counts are greater than 15,000/mm³. Band forms often exceed 15% of the total. Infants frequently exhibit an immature-to-total neutrophil ratio greater than 0.5.^{1,128,139} An absolute monocytosis

*References 17, 40, 50, 54, 81, 120, 127, 128, 138, 139, 142, 174, 179, 212, 229.

may be seen in two thirds of patients.¹²³ Culture-negative cerebrospinal fluid pleocytosis can occur.¹

Radiologic examination by upper gastrointestinal barium studies in 24 adult patients with severe diarrhea caused by *Y. enterocolitica* showed abnormalities of the terminal ileum in 21 cases.²¹⁷ Diffuse thickening of the mucosal folds was seen in 16 cases, and nodular filling defects were seen in 11. The radiographic appearance suggested the presence of one or more ulcerations of the terminal ileum in 11 patients. Dilation of the terminal ileum was noted in 12 patients, and extrinsic compression, presumably from enlarged lymph nodes, was present in four. In some instances, the findings suggested the terminal ileitis of Crohn disease. Follow-up studies performed 2 months after acute illness showed decreased but persistent thickening of mucosal folds in eight patients. Barium enema studies were done in 15 patients and showed no striking abnormalities other than mucosal ulcerations, which were seen best on air-contrast studies.²¹⁶

Mesenteric lymphadenopathy can be seen on computed tomography scans.²¹⁵ Among 13 adults who had colonoscopy or sigmoidoscopy for severe diarrhea caused by *Y. enterocolitica*, abnormalities were seen in eight; the mucosa appeared diffusely swollen, erythematous, and friable in six individuals, and two had only small, 1- to 2-mm aphthoid ulcerations. Serial procedures showed macroscopic and microscopic healing of ulcers within 4 to 5 weeks.²¹⁷ Mucosal ulcers may develop in the ileum and aphthoid ulcerations may be seen throughout the colon (Fig. 113.2).²¹⁵

Pseudoappendicitis-Mesenteric Adenitis

The syndrome of pseudoappendicitis, characterized in most cases by a normal appendix and an intense suppurative mesenteric adenitis, has attracted considerable attention since it was reported first in 1953.^{143,144} The first recognized cases were caused by *Y. pseudotuberculosis*, but most cases reported in recent years have been caused by *Y. enterocolitica*.^{30,103,127}

Fever, abdominal pain, right lower quadrant tenderness, and leukocytosis are the primary features of *Y. enterocolitica*-induced pseudoappendicular syndrome.^{50,104} Some patients also have features of enterocolitis (i.e., nausea, vomiting, and diarrhea). The clinical presentation often is highly suggestive of acute appendicitis, such that laparotomy is required. Among a series of 581 patients in Scandinavia who underwent laparotomy for suspected appendicitis, 3.8% of cultures of stool or operative specimens yielded *Y. enterocolitica*.¹⁵⁹ Another 284 patients with similar symptoms were observed, and 5.6% of stool cultures from

FIG. 113.2 Surgical specimen from a 12-year-old girl with 6 days of fever and abdominal pain localizing to the right lower quadrant. The proximal colon (left) shows evenly distributed aphthoid ulcers and a normal appendix (lower left). The terminal ileum (right) shows ulcers of varying size with normal intervening mucosa. (From Gleason TH, Patterson SD. The pathology of *Yersinia enterocolitica* ileocolitis. *Am J Surg Pathol*. 1982;6:347–55.)

these cases yielded *Y. enterocolitica*. In a similar Scandinavian series of 205 patients who underwent appendectomy, 22 subsequently were diagnosed by serology as having *Y. enterocolitica* infection.¹⁰⁴ The findings on laparotomy usually are mesenteric lymphadenitis, terminal ileitis, and a normal or slightly inflamed appendix.^{19,50,104,159}

A study of 40 cases of granulomatous appendicitis found evidence suggesting infection caused by *Y. enterocolitica* in four specimens, *Y. pseudotuberculosis* in four specimens, and both in two specimens by PCR analysis.¹²⁶ Two patients in the series subsequently were diagnosed as having Crohn disease, but causation cannot be inferred.

Asymptomatic Infection

In an unknown number of cases, infection by *Y. enterocolitica* is entirely asymptomatic. In a study of the distribution of antibodies to *Y. enterocolitica* in sera collected for various purposes in Ontario, Canada, from 4209 individuals who had no evidence of infection by this organism, specific antibody was present in 199 (serotype O:3 in 158 and serotype O:9 in 41).²¹²

Other Presentations of Acute Infection

Bacteremia can occur^{34,41,50,150} and may result in spread of infection to virtually any body site. Such events occur uncommonly and are seen more often in adults than in children. In children, bacteremia occurs more commonly in infants than in older children.¹ The risk for development of bacteremia during gastroenteritis in infants younger than 3 months may be 30%.¹⁵⁴ Bacteremias may be transient and asymptomatic or lead to septic shock and death. Septic cases tend to occur among patients with underlying illnesses and are associated with mortality rates of 34% to 50%.⁵⁰

Y. enterocolitica may cause focal infections in many extraintestinal sites, even in the absence of detectable bacteremia. Pharyngitis has been reported and occurs primarily in adults. Cervical adenopathy may be associated with *Y. enterocolitica* pharyngitis, and gastrointestinal symptoms may be absent.⁵⁰ One adult with pharyngitis died of associated septic shock.¹⁸¹ Conjunctivitis and panophthalmitis caused by *Y. enterocolitica* have been described. Parinaud oculoglandular syndrome,⁴² inguinal adenopathy,²²⁵ and suppurative lymphadenitis²¹⁴ have been reported, including a neonate with inguinal adenitis.¹⁶⁰

Cellulitis, soft tissue abscesses, and wound infections also have been reported. Cellulitis may have associated vesiculobullous lesions. An erysipelas-like rash, maculopapular rash, and urticaria also have been described in association with infection caused by *Y. enterocolitica*.^{17,30,50,77,189,206,226}

Pancreatitis, cholecystitis, diverticulitis, and intestinal perforation have been described.^{131,170} Peritonitis also can occur but is extremely rare,¹⁷⁵ especially considering the frequency of mesenteric adenitis. Pneumatosis intestinalis has been reported in an infant.¹ Pneumonia, pleural empyema, lung abscess, hepatic and splenic abscesses, urinary tract infection, and renal abscess also have been reported.⁵⁰ Glomerulonephritis that usually is transient has been reported.^{51,64} Cases of meningitis, osteomyelitis, septic arthritis, pyomyositis (including psoas muscle abscess), endocarditis, mycotic aneurysm, and intravenous catheter-related infection caused by *Y. enterocolitica* have been described.^{11,31,50,90,198,200} Thrombocytopenia⁶⁹ and hemolytic anemia¹¹⁸ have occurred in association with infection caused by *Y. enterocolitica*.

Underlying Conditions That Predispose to Bacteremia

Y. enterocolitica bacteremias that occur in patients beyond early infancy most often occur in patients with chronic illnesses or iron overload states. Thalassemias are such conditions that occur most commonly in children.^{40,62,110} Among 144 Italian children with thalassemia who were receiving deferoxamine therapy and frequent blood transfusions, 14 developed infection caused by *Y. enterocolitica* during a 12-month period.⁴⁰ Septicemia occurred in five of the 14 and was preceded by enterocolitis or mesenteric adenitis in each case. All 14 recovered after receiving 2 weeks of therapy with intravenous trimethoprim-sulfamethoxazole. A similar proportion of children with thalassemias observed in two centers in Canada between 1979 and 1994 also developed invasive disease caused by *Y. enterocolitica*.⁶ Bacteremia can be associated temporally with blood transfusions in such patients, suggesting that

transfusions may be the source of infection or predispose to development of infection in some cases.¹³¹

Hemochromatosis, cirrhosis, and other liver diseases may facilitate development of *Y. enterocolitica* bacteremia, also on the basis of excess availability of serum iron. Deferoxamine therapy itself is a risk factor for development of sepsis caused by *Y. enterocolitica* because of the ability of the microbe to extract iron from this compound. Immunosuppressive therapies, diabetes mellitus, and malnutrition also may predispose to development of *Y. enterocolitica* bacteremia.⁵⁰

Postinfectious Syndromes

A reactive arthritis may occur 1 to 14 (usually 4–10) days after the cessation of acute illness.^{7,8,10,12,90,92,179,209,217,227} Most such events occur in adults, with a slight female predominance, but 8 of 74 cases in one series from Sweden were in children aged 11 to 20 years (five boys, three girls).²²⁷ In a series from The Netherlands, 10% of children with yersiniosis, most of whom were 7 years of age or older, developed arthritis.⁹² The knees, ankles, and wrists are affected most commonly, and in approximately 50% of cases, only one or two joints are involved. Hands, fingers, toes, shoulders, hips, and elbows also may be involved. Pain usually is severe, and the arthritis is additive and usually not migratory. The inflammatory process is self-limited and may persist for 2 months or longer in two-thirds of cases, with one-third persisting for 4 months or longer.

The erythrocyte sedimentation rate exceeds 60 mm/h in approximately 50% of cases. Joint effusions usually are inflammatory, but cell counts and differentials vary and occasionally mimic septic arthritis. Immune complexes have been found in joint fluid. Nonsteroidal antiinflammatory drugs and corticosteroids, intraarticularly and systemically administered, have been used for symptomatic relief for this process.¹⁷⁸

Erythema nodosum also occurs as a postinfectious manifestation, more often in adults than in children. It can occur alone or in association with arthritis.⁸⁶ Tendinitis, myositis, myocarditis, urethritis, uveitis, and conjunctivitis also can occur in association with arthritis. Many but not all patients who develop these postinfectious reactions are human leukocyte antigen (HLA)-B27 positive.¹ Some patients manifest full Reiter syndrome.^{92,119,184,196} Acute glomerulonephritis has been linked to infection with serotype O:3 strains in one series of adults.⁶⁴

Yersinia antigens, but not intact bacteria, have been found in synovial tissue obtained several weeks to months after onset of reactive arthritis. *Y. enterocolitica* is able to survive within in vitro cultures of human synovial cells for 6 weeks, with resultant deposition of residual antigen aggregates within the cells.⁹⁸ Synovial fluid–derived T cells from patients with *Y. enterocolitica*–induced reactive arthritis have been shown to respond to several *Y. enterocolitica* antigens: heat shock protein 60, urease β subunit, ribosomal L2 protein, and a region of the plasmid-encoded tyrosine phosphatase YopH that is highly homologous to the catalytic domain of eukaryotic protein tyrosine phosphatases.^{124,145,168}

Epitopes on *Yersinia*-produced proteins likely trigger cross-reactive immunologic recognition of host proteins that leads to chronic inflammation in susceptible individuals.⁹⁵ High levels of antibodies that react with 60-kDa recombinant *Yersinia* heat shock protein have been found in HLA-B27–positive individuals with acute anterior uveitis or pars planitis.³³

Antibodies against *Y. enterocolitica* have been detected in patients with disorders of the thyroid, including Graves disease, thyroid adenoma, and Hashimoto thyroiditis.¹⁹⁰ A Danish twin study found no increased risk for thyroid antibodies after *Y. enterocolitica* infection, however.⁸⁴ These observations may reflect autoantibodies that cross react with *Yersinia* epitopes, rather than a causal link between yersiniosis and thyroid disease.^{50,176}

Yersinia pseudotuberculosis

The pseudoappendicular syndrome that results from mesenteric adenitis is the primary disease produced by *Y. pseudotuberculosis*.^{*} The chief complaint is abdominal pain, either diffuse or localized to the right

lower quadrant. Fever (38°–40°C) (100.4°–104°F) almost always is present. Tenderness over the McBurney point usually is present. All of these symptoms are highly suggestive of acute appendicitis. Diarrhea may occur but often is absent. Mild leukocytosis occurs, but white blood cell counts usually are less than 20,000/mm³. The clinical course almost always is benign, with recovery typically beginning approximately the fifth day of illness. On laparotomy, the appendix is normal in most cases but occasionally appears inflamed or suppurative. The mesenteric lymph nodes are enlarged and may appear necrotic.

Efforts have been made to distinguish the pseudoappendicular syndrome caused by *Y. pseudotuberculosis* from that caused by *Y. enterocolitica*.^{26,70} *Y. pseudotuberculosis* adenitis is less likely to have associated enterocolitis and may have a shorter febrile course but no clear distinction can be made on clinical grounds alone.

A fulminant typhoidal or septicemic form of infection caused by *Y. pseudotuberculosis* can occur but seems to affect primarily older adults with debilitating conditions, such as diabetes or liver disease. This syndrome often is fatal.^{115,184} Isolated cervical adenitis, liver abscess, and terminal ileitis have been described.^{86,224} Subacute and recurrent disease can occur.¹³⁷ Erythema nodosum¹⁸⁴ and nonsuppurative arthritis³⁹ also have been reported in association with infection caused by *Y. pseudotuberculosis*. In an outbreak related to eating contaminated grated carrots in Finland in 2003, erythema nodosum was seen in numerous patients with gastrointestinal illness.¹⁰² Median time from exposure to development of gastrointestinal symptoms was 8 days. Median time from exposure to development of erythema nodosum was 19 days (see Fig. 113.2). One patient developed reactive arthritis in a similar time frame.

Yersinia pseudotuberculosis and Kawasaki Disease–Like Illness

In Korea and Japan, *Y. pseudotuberculosis* strains have been responsible for a clinical syndrome that can mimic Kawasaki disease.³⁹ This manifestation of disease occurs primarily in outbreaks and has been described as scarlet fever–like.¹⁶³ A transient (2–3 days) erythematous maculopapular rash, strawberry tongue, conjunctivitis, and desquamation can occur, generally in association with gastrointestinal symptoms and fever. Erythema nodosum, lymphadenopathy, uveitis, and coronary aneurysms have occurred in some of these cases, as has acute interstitial nephritis, which can lead to transient renal failure.^{3,122,163} Among a series of 33 patients (median age, 5 years) with such presentations, 20 had elevated antibody titers against *Y. pseudotuberculosis*–derived mitogen, which can function as a superantigen.³ As in Kawasaki disease, V β 3 T lymphocytes were increased in many of these patients in contrast to healthy control subjects.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of *Yersinia* enterocolitis includes viral and other bacterial causes of acute gastroenteritis. When the symptoms of mesenteric adenitis are predominant and severe, appendicitis and other causes of an acute abdomen must be considered. The acute terminal ileitis caused by *Yersinia* infections also can be similar to the gastrointestinal manifestations of Crohn disease, ulcerative colitis, cat scratch disease, anisakiasis, amebiasis, actinomycosis, typhoid fever, and lymphoma.^{68,92,163,216,224} Cases of infection caused by *Y. enterocolitica* with concomitant recovery of *Salmonella* and *Campylobacter* spp. and rotavirus antigen in stool specimens have been observed.¹

DIAGNOSIS

The most effective approach to the diagnosis of yersiniosis is isolation of the organism from the stool of patients with enteritis caused by *Y. enterocolitica* or from the infected mesenteric lymph nodes of patients infected by *Y. pseudotuberculosis*. *Y. enterocolitica* occasionally can be recovered from involved mesenteric lymph nodes or the distal ileum.⁵⁰ Cultures of feces from individuals with acute suppurative mesenteric adenitis usually fail to grow either organism.

Isolating *Yersinia* organisms from extraintestinal specimens such as lymph nodes and blood is not difficult because they grow on ordinary media (e.g., blood agar) and on several selective and differential media

*References 20, 53, 61, 70, 91, 96, 114, 115, 137, 163, 183, 184, 219, 224.

employed for enteric bacteria. Isolating from fecal specimens is more difficult, however, because *Yersinia* multiply more slowly than other enteric bacteria at 37°C (98.6°F) and have no characteristic colony morphology. Selective media have been developed, but many clinical laboratories culture stool specimens for *Yersinia* spp. only on request because of the costs of these media and the relatively low frequency of occurrences of these pathogens in the community.

Yersinia organisms grow well on MacConkey agar but are much smaller than are other enteric bacteria after standard incubation at 37°C. Cefsulodin-irgasan-novobiocin agar plates have been designed specifically for the isolation of *Yersinia* spp. from stool specimens. After being incubated for 48 hours, *Yersinia* colonies appear dark pink with translucent borders and occasionally are surrounded by a zone of precipitated bile. Cefsulodin-irgasan-novobiocin agar inhibits the growth of most other bacteria except for *Citrobacter* spp. (positive citrate reactions of which allow their distinction). If a dedicated medium for *Yersinia* isolation is not used, MacConkey agar can be examined after 24 hours at 35° to 37°C (95°F–98.6°F) for small colorless colonies that become much larger after an additional 24 hours of incubation at room temperature. Most *Y. enterocolitica* strains are lactose-negative.⁷³ *Yersinia* spp. grow faster at 37°C than at room temperature. Growth occurs readily at 22° to 28°C (71.6°F–82.4°F), however, and these lower temperatures are recommended for primary isolation.⁷³ Because of the ability of *Yersinia* spp. to grow at even colder temperatures, specimens can be inoculated into phosphate-buffered saline, refrigerated at 4° to 6°C (39.2°F–42.8°F), and subcultured periodically (up to 4 weeks) if the routine plates that were inoculated with the specimen remain negative. Such “cold enrichment” greatly enhances the isolation rate of *Yersinia* spp. and may be the most reliable method for isolating these organisms from fecal specimens. Many of the *Yersinia* isolates recovered by cold enrichment represent either *Y. enterocolitica* serotypes that usually are not associated with human disease or other *Yersinia* spp. that have roles in disease that remain unclear.

Pathologic or virulent *Yersinia* strains can be distinguished in most instances from nonpathogenic strains by three biochemical tests that are associated with absence of the virulence plasmid. The virulent strains lack pyrazinamidase activity, do not ferment salicin, and do not hydrolyze esculin. On Congo red–magnesium oxalate agar during incubation at 36°C (96.8°F), fresh pathologic isolates (but not those that have been subcultured serially) grow as small red colonies, showing the virulence plasmid-determined properties of Congo red dye uptake and calcium-dependent growth.⁵⁹

Serology

Serology can be performed with microtiter techniques and is most reliable for serotypes O:3 and O:9 of *Y. enterocolitica*. Antibody to the infecting serotype usually is absent at the onset of disease. Peak titers usually are reached 3 to 4 weeks after onset of clinical illness and decrease during the next 3 to 5 months. Low postconvalescent titers may persist for months. Microhemagglutination, complement fixation, and enzyme immunoassays are available in a few commercial laboratories.^{27,73,216}

Agglutinin titers of 1:128 or higher for *Y. enterocolitica* in previously normal healthy individuals suggest infection. Titers of 1:200 or greater were present within 3 weeks of onset of illness in 62 of 65 Canadian children who had infection with serotype O:3. Fourfold increases in titer rarely were seen. Negative or minimal titers (≤1:32) do not rule out yersiniosis in infants or immunosuppressed patients. Serologic responses occur more commonly and are of higher titer among patients with extraintestinal systemic infection. Prozone reactions may occur at dilutions of 1:32 or lower. Marked cross agglutination occurs between *Y. enterocolitica* serotype O:9 and *Brucella abortus*, *Morganella morganii*, and *Salmonella*.^{27,142} Antibodies to *Y. pseudotuberculosis* often are detectable at the onset of clinical signs of infection and may be highest during the acute phase of illness.⁹¹

Molecular Techniques

PCR assays have been developed for *Y. enterocolitica* and *Y. pseudotuberculosis* with use of primers that allow assessment of 16S rRNA sequences and of specific plasmid-encoded and chromosome-encoded

genes.^{39,126,155,156,220,222} PCR techniques have been used to identify *Yersinia* organisms in blood, tissue, stool, water, and food samples.^{85,125} *Y. enterocolitica* can be detected by several commercially available multiplex PCR panels marketed for detection of common bacterial, viral, and protozoan pathogens in stool specimens.¹¹²

TREATMENT

Most patients with yersiniosis do not require treatment because the disease usually is self-limited. Seriously ill patients generally have responded to treatment with chloramphenicol, gentamicin, or tetracyclines, but clinical success has not been uniform. Of these agents, tetracyclines have been the traditional agent of choice.^{70,216} *Y. enterocolitica* isolates resistant to the tetracyclines have been reported in recent years, however. Two percent of a sample of *Y. enterocolitica* isolates from Canada in 1992 were resistant to tetracycline,¹⁶⁷ and 10% of a sample of *Y. enterocolitica* isolates from the Netherlands from 1982 to 1991 were resistant to doxycycline.²⁰²

More than 99% of 1060 isolates of *Y. enterocolitica* collected in Canada in 1972 to 1976, 1980, 1985, and 1990 were susceptible in vitro to piperacillin, cefotaxime, aztreonam, gentamicin, tobramycin, amikacin, trimethoprim-sulfamethoxazole, chloramphenicol, and ciprofloxacin. No evidence of decreasing susceptibility to any of these agents was found across the periods sampled. These results were mirrored by a study of 335 isolates obtained in the Netherlands from 1982 to 1991. All of these isolates were susceptible to ceftazidime, cefepime, imipenem, trimethoprim-sulfamethoxazole, ciprofloxacin, and ofloxacin. Aminoglycosides were effective against more than 99%, chloramphenicol was effective against 94%, and cefuroxime was effective against 90%. Seven multidrug-resistant isolates were present among the isolates from Canada, but none was found among the isolates from the Netherlands.^{167,202}

Most *Y. enterocolitica* isolates, regardless of serotype, are resistant to ampicillin, ticarcillin, and first-generation cephalosporins. Most of them also are resistant to amoxicillin-clavulanic acid. This is likely due to expression of β -lactamase *BlaA* and/or *BlaB* genes, because most *Y. enterocolitica* strains harbor both.²¹ Azithromycin was active in vitro against 50% of the 335 isolates in the Netherlands, but almost all isolates were resistant to erythromycin and clarithromycin.^{167,202} Antimicrobial resistance of *Y. enterocolitica* strains in Europe does not appear to have increased in recent years.²¹

The decreasing effectiveness of tetracyclines in vitro raises the question of whether these agents should be the first choice for treatment of infection caused by *Y. enterocolitica*. A retrospective review of 43 cases (with patient ages ranging from 3 to 89 years) treated for *Y. enterocolitica* septicemia in France between 1985 and 1991 showed that third-generation cephalosporins were effective in 85% of cases in which they were used, although aminoglycosides or fluoroquinolones usually were administered concurrently.⁶⁵ Fluoroquinolones alone or in combination with other agents cured all 15 patients. Seven children with bacteremia and diarrhea in Michigan responded well to cefotaxime.¹

In a double-blind, placebo-controlled trial of trimethoprim-sulfamethoxazole for treatment of children with gastroenteritis caused by *Y. enterocolitica*, the clinical course of illness was not shortened.¹⁶⁵ The children had been ill for a mean of 12 days before treatment was begun, however.

Systemic infections, extraintestinal focal infections, and enterocolitis in compromised hosts should be treated with antibiotics.⁵⁰ The in vitro susceptibilities and limited clinical data suggest that children with such infections should be treated with a third-generation cephalosporin, an aminoglycoside, or both. Trimethoprim-sulfamethoxazole also may be used.^{40,92} Fluoroquinolones also probably would be effective. Cefotaxime and ceftriaxone were effective in treating bacteremia in a series of 12 children.²

Even fewer clinical and in vitro susceptibility data are available for *Y. pseudotuberculosis*. These infections probably can be managed identically to *Y. enterocolitica* infections. A recent analysis of 12 strains in Germany found no resistance to agents tested, including ampicillin.²¹ All isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* should be examined for susceptibility to a variety of antibacterial drugs.

VACCINES

There are no vaccines for *Yersinia* species at this time in the United States, although a live attenuated *Y. pestis* vaccine is available in some countries.²⁰⁵ An attenuated *Y. pseudotuberculosis* strain (IP32953) transformed to express the *Y. pestis* F1 capsule conferred 100% protection in mice against a high challenge dose of *Y. pestis* after a single oral dose of the vaccine strain.⁵⁵

OTHER YERSINIA SPECIES

Other “non-pestis” *Yersinia* spp. (*Y. frederiksenii*, *Y. intermedia*, *Y. kristensenii*, *Y. aldovae*, *Y. bercovieri*, *Y. mollaretii*, *Y. rohdei*, *Y. alecksiciae*, *Y. similiensis*, *Y. massiliensis*, and *Y. ruckeri*) occasionally have been isolated from clinical specimens, but their roles as human pathogens remain unclear.^{73,189,191,203} These microbes also can be found in fresh-water sources, sewage, dogs, pigs, cattle, wild mammals, birds, reptiles, fish, and some foods, especially milk and meat products.

These organisms are similar biochemically to one another and have been termed atypical *Y. enterocolitica*.⁵⁰ None contains the *Yersinia* virulence plasmid pYV.¹⁴⁶ Some contain other large plasmids distinct from pYV, carriage of which may be associated with the ability to cause diarrhea in humans.^{164,203} A heat-stable enterotoxin has been found in isolates of *Y. bercovieri*.²⁰⁴ These *Yersinia* spp. can grow at 4°C (39.2°F) and on cefsulodin-irgasan-novobiocin agar and can multiply in refrigerated foods.

These species occasionally may cause diarrhea and other gastrointestinal symptoms, especially in immunocompromised hosts or individuals with gastric acid suppression.¹³⁴ Use of cold enrichment techniques may enhance recovery of these organisms. Their isolation from clinical specimens should not be disregarded or deemed causative of clinical disease without careful epidemiologic considerations.⁷³ Isolates of these species sometimes can be misidentified as *Y. enterocolitica* by commercial identification systems used in many clinical laboratories. Differences in colony morphology, pyrazinamide reactions (negative for *Y. enterocolitica*), and other biochemical tests can be used to distinguish them from *Y. enterocolitica*.^{80,109}

Miscellaneous Enterobacteriaceae

114

Randall G. Fisher

Three less commonly isolated organisms of the family Enterobacteriaceae are *Edwardsiella tarda*, *Hafnia alvei*, and *Pantoea agglomerans*. Each of these organisms, although uncommon, can cause significant disease in certain clinical circumstances.⁷⁵

EDWARDSIELLA TARDA

Bacteriology

E. tarda is a non-lactose-fermenting, gram-negative bacillus that is indole positive and produces hydrogen sulfide. It ferments only glucose and maltose. The species name *tarda* reflects its biochemical inactivity. Most, if not all, *E. tarda* isolates have peritrichous flagellae (from one to about seven); a higher number of flagellae correlates with better motility and improved biofilm formation in vitro.⁴³ It usually is lysine positive and ornithine decarboxylase positive.³⁰ The organism resembles *Salmonella* biochemically and clinically.⁴⁹ *Salmonella* usually ferments mannitol, sorbitol, and rhamnose, however. The innate resistance of *Edwardsiella* to colistin also distinguishes it from *Salmonella*.⁷⁸ *E. tarda* grows well on usual differential media in the laboratory and produces smooth, glistening, semitranslucent colonies.

Epidemiology

E. tarda is an organism associated with freshwater and marine life and has been isolated from turtles, fish, pelicans, alligators, seals, and toads.⁴⁹ It also is found in snakes and lizards. Case reports of human disease have implicated ornamental fish,¹⁰⁷ pet turtles,⁷⁹ snakes,⁹¹ and catfish^{8,20,41} and injuries in fresh and brackish water.⁹⁸

Patients with chronic liver disease, chronic ethanol abuse, corticosteroid therapy, and hemoglobinopathy particularly are prone to developing infection with *E. tarda*.⁶⁸ Any condition associated with iron overload

also is a potential risk factor. Serious infections, including pyomyositis and bacteremia, can occur even in otherwise well individuals.^{40,98} A single case of infected distal aortic arch aneurysm has been reported.⁸³

Infection with *E. tarda* is global but occurs more commonly in tropical and subtropical climates, particularly Southeast Asia, Africa, and Latin America.⁵⁷ The elderly and the very young seem to be at increased risk for developing severe illness.¹² Asymptomatic carrier states have been documented as well,⁸⁵ but no true epidemic has been reported, and person-to-person transmission has not been established directly.²⁷

Pathophysiology

Invasiveness of the organism in HeLa and HEp-2 cells,⁸⁸ siderophore production, the elaboration of a cell-associated hemolysin,⁴⁴ and resistance to complement-mediated lysis may contribute to virulence, although no clear associations have been made.⁵³ Hemolytic activity requires the presence of two genes, *ethA* and *ethB*. The *ethA* gene codes for the hemolysin, whereas the *ethB* gene codes for an activation/secretion protein, which is necessary for activation of the hemolysin. Transcription of the *ethB* gene is regulated by iron, which may explain the association between iron overload states and severe *E. tarda* infection.⁴⁴ Hemolysin activity seems to be necessary for cell entry and cytotoxicity.¹⁰¹ *E. tarda* produces an iron-cofactored superoxide dismutase that inhibits macrophage-mediated innate immune responses.¹⁸ *E. tarda* has both type III and type VI secretion systems; expression of these gene products is regulated by phosphorus and iron concentrations.¹⁶

Clinical Manifestations

Infections with *E. tarda* can be divided broadly into two types: intestinal and extraintestinal. Approximately 80% of infections are intestinal.⁹⁸ Gastrointestinal infection usually causes self-limited enteritis, with

intermittent watery diarrhea and low-grade fever.⁴⁷ Nausea and vomiting usually are not seen. Occasionally enterocolitis or a dysentery-like illness is noted.⁷¹ Because most laboratories do not culture stool specimens specifically for *Edwardsiella*, most cases are unrecognized.

Wound infection is the most common extraintestinal infection. Most of the wounds are caused by fish fins or snakes; wounds sustained in automobile accidents also have been implicated.⁵⁰ Cellulitis or abscesses may be produced. Coinfection with other organisms, particularly *Aeromonas hydrophila*, is common.^{41,98} One case of necrotizing fasciitis and myonecrosis in an immunocompetent man has been reported. Cultures obtained at surgical debridement yielded a pure growth of *E. tarda*.⁹⁸ In one case, a puncture wound from a catfish led to a rapidly progressive, necrotizing soft tissue infection in a man with chronic active hepatitis C infection; after failing multiple debridements, he received a transhumeral amputation.²³

Septicemia with *E. tarda* is a rare but serious infection that carries a mortality rate of approximately 45%. Most patients with septicemia have underlying conditions, such as liver disease, iron overload, diabetes mellitus, and immunosuppression. Septicemia occasionally follows a mild diarrheal illness.²⁰ Infants without other risk factors have been reported.¹⁰⁸ Septicemia manifests as high fever, shock, and, often, disseminated intravascular coagulation. Meningitis and multiple brain abscesses also have been reported.^{84,95,102,110} Death sometimes occurs despite administration of appropriate antimicrobial therapy.

Other syndromes associated with *E. tarda* infection include an enteric fever-like illness,²⁰ multiple or solitary liver abscesses,^{59,115} osteomyelitis,⁹¹ septic arthritis,⁸ cellulitis,³⁴ myonecrosis,⁹⁸ necrotizing fasciitis,⁷⁴ endocarditis,⁸⁰ uterine pyomyoma,¹¹³ tubo-ovarian abscess,⁸⁹ and peritonitis.²⁰ A case of puerperal intrauterine infection in a woman without obvious risk factors has been reported; her infant was not affected.⁷⁶ In another case, neonatal sepsis resulted from maternal chorioamnionitis.⁴² Patients with sickle-cell disorders may be predisposed to bony infection with *E. tarda*, as they are with *Salmonella*.^{95,112} Reported cases all are in patients with sickle-cell hemoglobinopathy, rather than homozygous sickle-cell disease. Osteomyelitis has also been reported in X-linked chronic granulomatous disease.⁵⁵

Diagnosis and Treatment

Diagnosis rests on identification of *E. tarda* in culture. The major pitfall is mistaking it for *Salmonella*.

E. tarda is sensitive in vitro to most antibiotics used routinely in the treatment of gram-negative infections, including β -lactams, cephalosporins, aminoglycosides, and fluoroquinolones.¹⁹ It also is sensitive to chloramphenicol, trimethoprim-sulfamethoxazole, and tetracycline.¹⁰⁰ Resistance to polymyxin B, colistin, and, occasionally, penicillin has been shown.^{19,20} The organism almost universally elaborates a β -lactamase, but no resistance to β -lactams other than penicillin¹⁹ and oxacillin¹⁰⁰ has been reported.

Gastrointestinal disease usually does not require treatment. Severe disease, such as septicemia or meningitis, probably should be treated with the combination of a β -lactam and an aminoglycoside,⁴⁹ even though synergy has not been shown.

HAFNIA ALVEI

Bacteriology

H. alvei is a facultatively anaerobic, gram-negative bacillus, formerly referred to as *Enterobacter hafnia*.⁹⁶ This indole-negative, catalase-positive, and oxidase-negative organism is positive for lysine and ornithine decarboxylases. It is motile at lower temperatures but may be immotile at temperatures of 35°C (95°F) and greater. *H. alvei* ferments mannitol, maltose, and sucrose. It grows well on blood or MacConkey agar as a nonlactose fermenter, producing gray-white, slightly elevated, glistening colonies.²⁹ Historically *H. alvei* was thought to be the only species within the genus *Hafnia*; however, in 2010, members of DNA hybridization group 2 were reclassified as *H. paralvei* sp. nov.⁴⁵

Epidemiology

H. alvei has been found in soil, dairy products, sewage, and the feces of humans and animals. Some question whether it exists as part of the

endogenous microflora of the gut⁹² or whether an asymptomatic “carrier” state exists. One study from Japan cultured *H. alvei* from 13% of healthy subjects⁷³; other epidemiologic surveys have shown the incidence to be less than 2%.⁹⁴ Long regarded as a nonpathogen, *H. alvei* now has been associated clearly with enteritis and rarely has been isolated in pure culture from other sites, including blood, cerebrospinal fluid, peritoneal fluid, and urine. Infection seems to be opportunistic.

Pathophysiology

The pathophysiology of *H. alvei* has been investigated most thoroughly with regard to its production of gastrointestinal symptoms,³ although whether *H. alvei* is actually a diarrheagenic pathogen remains controversial. Albert and associates⁴ showed that although *H. alvei* elaborated neither enterotoxins nor a Shiga-like toxin and was not invasive in HeLa cell assays or by Sereny test, it did produce diarrhea in experimental animals whether given parenterally or by mouth. Sections of intestines from infected animals showed lesions indistinguishable from those caused by enteropathogenic *Escherichia coli*. “Diarrheagenic strains” of *H. alvei* also were thought to differ from other strains in that they possessed the *eaeA* gene.⁴⁷ Janda and colleagues⁵² first presented data suggesting that diarrheagenic *H. alvei* isolates were actually either unusual biotypes of *E. coli* or a new species in the genus *Escherichia*. Subsequently the same group showed that organisms originally called *H. alvei* reported to produce attaching-effacing lesions and to possess the *eaeA* gene are actually a novel species, *Escherichia albertii*.⁴⁶ *H. alvei* does cause damage to intestinal epithelial cells but does not use the attaching-effacing mechanism, nor does it use the same mechanism as *E. coli* O157:H7.²⁸ Information about the pathophysiology of extraintestinal infection is sparse.⁵¹

Clinical Manifestations

Cases of diarrhea caused by *H. alvei* (possibly *E. albertii*) have been reported primarily in children.^{3,4} Most patients with gastroenteritis secondary to *H. alvei*/*E. albertii* report six to 12 episodes of watery diarrhea per day, low-grade or no fever, and nausea with or without vomiting. Mucus sometimes is found in stools, but blood is not.^{92,111} In most patients, symptoms last for a few days, but in some patients, symptoms persist for more than a week.⁹² One patient with a reactive arthritis from *H. alvei*/*E. albertii* enteritis has been reported.⁸¹ A unique case has been reported of an 11-year-old girl who had a 3-day history of red lesions on the forehead, neck, and trunk associated with abdominal pain, emesis, and decreased urinary output, with one bloody diarrheal stool the day before admission; she then developed hemolytic-uremic syndrome. Stool cultures repeatedly were negative for *E. coli* O157:H7 but positive for a toxigenic strain of *H. alvei* from two consecutive cultures.²²

Traditionally extraintestinal *H. alvei* infections were thought to occur mostly in hospitalized patients and to be hospital acquired. In one large series, the organism was isolated from 80 samples collected from 61 patients; 57 (93%) patients had underlying illnesses, most commonly malignancies.³⁸ Nearly half of isolates were from the respiratory tract. Other sites included blood, skin, wounds, urine, and intraabdominal abscesses. In 60 (75%) samples, other organisms were cultured concomitantly. In a larger study from Canada, two-thirds of 138 isolates were of community onset, 112 (81%) were from the urinary tract, and 94 (68%) were from monomicrobial infections.⁶⁰ Older age and female gender were risk factors for development of infection.

One 20-day-old premature infant with necrotizing enterocolitis exhibited *H. alvei* in blood and stool.³⁶ Yeager and associates¹¹⁴ reported four cases of pneumatosis intestinalis in patients after they had undergone bone marrow transplantation; in one of the four cases *H. alvei* was grown in pure culture from blood. An 8-year-old boy with acquired immunodeficiency syndrome (AIDS) developed recurrent episodes of *H. alvei* bacteremia.²¹ Both episodes were associated with fever and diarrhea; the second episode also was associated with pneumonia and pleural effusion, the cause of which is unclear. A well-documented case of pneumonia in a 54-year-old woman with AIDS has been reported in which the pleural fluid grew a pure culture of *H. alvei*.³¹ A patient with graft-versus-host disease developed *H. alvei* colonization with mild symptoms suggesting infection.⁹⁷ Pyelonephritis⁶⁴ and gangrenous

cholecystitis⁸⁷ have been reported. A 39-day-old infant without obvious risk factors developed urosepsis.⁶³ A single case report of *H. paralvei* bacteremia, in an 85-year-old man, exists. His culture was also positive for an enterococcus.⁸⁶

Wound abscess caused by *H. alvei* has been reported.² A 2-year-old liver transplant recipient developed hepatic abscess and bacteremia with *H. alvei* and *Enterococcus faecalis*.⁹ One case of meningitis in a 1-year-old infant without known predisposing risk factors has been reported.⁷⁷ A case of a woman with rheumatoid arthritis who contracted endophthalmitis with *H. alvei* in mixed culture has been described; the woman used snake powder as a food seasoning.¹⁵ Two case reports are described in the older literature of persistent bacteremia with this organism, alone and in mixed cultures. One of these patients was a previously well 13-year-old girl.³⁷

Diagnosis and Treatment

Diagnosis is established by isolation of the organism from stools or from normally sterile body fluids. Gunthard and Pennekamp³⁸ reported the susceptibility results of 80 *H. alvei* isolates recovered from 61 patients over a 2.5-year period. All isolates tested were susceptible to ciprofloxacin. Isolates also were generally susceptible to tobramycin (99%), imipenem (99%), piperacillin (92%), trimethoprim-sulfamethoxazole (90%), ceftriaxone (88%), and ceftazidime (88%). Nearly all isolates were resistant to ampicillin and to amoxicillin-clavulanate.

H. alvei is constitutively cephalothin resistant.¹¹¹ One report describes an inducible β -lactamase that rendered the isolate ceftazidime resistant.¹⁰³ In a study of 17 isolates from a single institution in France, six were noted to have a high-level constitutive, inducible cephalosporinase production profile similar to that of *Enterobacter* spp.³⁹ In one study, the antimicrobial susceptibility of *H. alvei* was compared with that of *E. albertii*, the organism with which *H. alvei* is confused most frequently. *E. albertii* isolates were naturally susceptible to all β -lactams except for penicillin and oxacillin; they also were susceptible to azithromycin. In contrast, *H. alvei* strains were naturally resistant to tetracycline, amoxicillin, amoxicillin-clavulanate, ampicillin-sulbactam, azithromycin, and the narrow-spectrum cephalosporins.¹⁰⁰ Most are also resistant to colistin.¹

Treatment probably is unnecessary for most cases of gastroenteritis. Treatment of invasive infection should be based on susceptibility testing. Empirical therapy with a third-generation cephalosporin and an aminoglycoside is reasonable pending susceptibility results.

PANTOEA AGGLOMERANS

First identified as a plant pathogen and named after Erwin Smith in 1917, the genus *Erwinia* has an extended domain as an infectious microbe, including production of disease in humans.^{14,90,99} A member of this group of organisms, *Pantoea agglomerans* (*Enterobacter agglomerans*, *Erwinia herbicola*) has been established as a cause of conjunctivitis,¹⁴ central nervous system infections,^{14,96} urinary tract infections,^{89,95} pneumonia,⁵ and nosocomial infections secondary to contaminated intravenous fluids.^{34,56} Other species in the genus *Pantoea* are extremely rare causes of infection, including *P. dispersa*,³⁹ *P. ananatis*,⁶⁹ and *P. calida*.³⁵

Bacteriology

Species definition within *Erwinia* has been controversial and confusing. It has been suggested to rename the anaerogenic clinically relevant *Erwinia herbicola*-*lathryi* group *E. agglomerans* or *P. agglomerans*.^{30,49,99} In clinical microbiology, both of the latter terms tend to be used interchangeably. This species consists of facultatively anaerobic, fermentative, hydrogen sulfide-negative, gram-negative rods; they do not possess oxidase, phenylalanine deaminase, proteinase, or arginine dehydrolase.³⁰ None decarboxylates ornithine.⁴⁹ They are motile, have peritrichous flagella, and produce a yellow pigment. Strains grow well at 37°C (98.6°F) on standard agar. When colonies are viewed microscopically after growth for 18 to 20 hours, characteristic biconvex spindle-shaped bodies and bacterial aggregates often can be seen.^{14,96} Almost all strains isolated from clinical specimens and grown on agar slants show characteristic elongated, spheroidal aggregates,⁹⁸ termed *symplasmata* by Cruickshank,²⁴

who first described them. It is difficult to identify them to the species level without using molecular methods.⁹³

Epidemiology

Microorganisms of the genus *Erwinia* long have been recognized as phytopathogens producing dry necrosis, wilts, and soft rots in plants; more recently they have been associated with disease in trout and leafhoppers.^{90,99}

The first reports of *P. agglomerans* as a human pathogen appeared in the 1960s. Many infections are local skin/soft tissue infections or synovitis/septic arthritis cases from thorn injuries. Subsequently a nationwide outbreak of infection caused by this organism was traced to contaminated liners from caps of parenteral solution bottles.^{66,67} The importance of this organism as a nosocomial cause of bacteremia is emphasized by the 17% mortality rate in patients receiving an infusion with the contaminated intravenous fluid.⁶⁶ A trend was noted for an increased mortality rate in infected individuals younger than 20 years. In neonatal intensive care units, the situation seems to be even more dire; in one study, the mortality rate for infants with blood cultures positive for *P. agglomerans* was 88% (seven of eight).¹⁰⁶ Lipid-based medications support rapid bacterial growth at room temperature and, in the absence of strict aseptic handling, have been implicated in more recent nosocomial *P. agglomerans* bloodstream infections.¹¹ An outbreak of eight cases of bacteremia occurring in a 3-week period was traced to an anticoagulant citrate-dextrose solution that was prepared in house.¹³ *Pantoea* outbreaks also have been traced to contaminated blood products; prolonged storage of packed red blood cells at 4°C provides conditions that allow these organisms to grow and subsequently produce high concentrations of endotoxin.⁷ Cotton used to filter heroin has been implicated as a source of infection ("cotton fever") in intravenous drug users.³²

Outbreaks in pediatric hospitals and urgent care centers caused by contaminated intravenous solutions⁷² or tubing¹⁰ also have been described. At least one retrospective review of *Erwinia* organisms isolated from clinical specimens suggested a predisposition to infection in the pediatric age group¹⁴; however other studies have noted no preference based on season, sex, age, or residence in hospitals.⁹⁹ A large pseudo-outbreak traced to contamination of cotton pledgets also has been reported.⁵⁶

Pathophysiology

The true incidence of clinical infection caused by *P. agglomerans* is difficult to ascertain because of the common association of this microbe with other organisms when obtained from clinical specimens. Nonetheless the accumulation of case reports in which this organism is isolated in pure culture from infected material leaves little doubt that *P. agglomerans* can be a human pathogen, apart from its role as a nosocomial contaminant. This organism has little inherent invasiveness. Evidence for animal pathogenicity of *Erwinia* strains isolated from plants and humans is limited⁶²; 10¹⁵ washed organisms injected intraperitoneally into mice or guinea pigs do not cause symptoms, whereas inoculation of 10³⁰ organisms leads to death within 36 hours.²⁴

Most strains seem to act as saprophytes in humans,¹⁰⁹ but the organism has been isolated from purulent wounds of the extremities acquired through lacerations or thorn pricks. In one series of nine infected superficial wounds seen in an emergency department and not getting better more than 10 days later, *P. agglomerans* was responsible for all of them. Most failed antibiotic treatment for a month or more, leading to discovery of retained plant material; wounds healed within 2 to 3 days after said material was removed.¹⁰⁵ In one fascinating case, a 25-year-old man was found to have a mass in his right posterior thigh, thought to be a benign tumor. Biopsy specimens grew *P. agglomerans*. Upon further questioning, the man recalled a fall that had resulted in a thorn injury to the thigh some 4 years previously.⁴⁸ Thorn injuries also have led to septic arthritis and osteomyelitis.²⁵ A delay of 4 to 6 weeks often occurs between the injury and the bone or joint infection. In one case, an 8-year-old girl developed osteomyelitis due to *P. agglomerans* about a month after a closed fracture of the radius and ulna.⁵⁸ Most serious infections have occurred in individuals with a breach of host defenses (e.g., immunocompromised individuals or patients who received contaminated intravenous fluid).

Clinical Manifestations

P. agglomerans bacteremia often is associated with fever, shaking chills, and systemic toxicity characteristic of gram-negative sepsis. These symptoms frequently have been misinterpreted, however, in hospitalized patients who unknowingly were administered contaminated intravenous fluids.⁶⁷ Premature neonates with sepsis owing to *P. agglomerans* tend to have a rapidly progressive sepsis with prominent pulmonary involvement, including hemorrhage and acute respiratory distress syndrome. A case series of five premature infants with *P. agglomerans* bacteremia has been reported; all infants had a birth weight of less than 1500 g, and in all cases the onset of sepsis was after age 7 days. Lethargy, mottling, and bradycardia were common; patients had desaturations but no evidence of pulmonary disease. Thrombocytopenia developed in four of the five infants, with metabolic acidosis in two and jaundice in two.⁶ In the largest pediatric series reported to date, 21 of 53 (about 40%) *P. agglomerans* isolates from normally sterile sites were grown from central venous lines; of these, two-thirds were polymicrobial.²⁵

Eye and skin infections caused by *P. agglomerans* are particularly prominent. Bottone and Schneerson¹⁴ included six cases of conjunctivitis, five of which occurred in infants, from whom this organism was isolated. Only two of the isolates were in pure culture, however, and a description of the clinical course of these children was not included in the report. *Erwinia* endophthalmitis has been associated with foreign-body penetration of the eye in a 14-year-old boy.⁸²

Skin infection in association with a casted fracture has been described in an elderly patient,¹⁰⁹ and wound infections from which this organism was isolated have been described subsequently, most often in association with agricultural injury.¹⁰⁹ Four isolates were obtained in mixed cultures from skin lesions of children younger than 5 years, but their possible role in those infections was not confirmed.¹⁴ In a recent series, 14 cases of abscesses required drainage; all 14 were polymicrobial.²⁵ *P. agglomerans* was the only organism isolated from six consecutive blood cultures in a 9-year-old boy with osteomyelitis.⁷⁰ A 13-year-old boy developed septic arthritis caused by *P. agglomerans* 1 month after sustaining a plant thorn injury to his knee.²⁶ A case of *P. agglomerans* spondylodiscitis has been reported.⁹⁰ In many cases of *P. agglomerans* osteomyelitis or septic arthritis, the patient is afebrile and blood cultures are negative. In addition, measures of inflammation and joint fluid findings may be largely unremarkable.²⁵ A high index of suspicion of *P. agglomerans* must be maintained when bone or joint infection follows plant thorn injury.

Primary lung disease caused by these bacteria is a rare occurrence; it has been reported in an adult with chronic bronchitis⁶ and also in a heart-lung transplant recipient.⁶ This organism is a very rare cause of meningitis. A contaminated incubator has been implicated in two cases of neonatal central nervous system infection,¹⁰⁴ and a cisternal tap revealed the presence of *P. agglomerans* in an unrelated case in a newborn whose clinical course was not described.¹⁴ A 57-year-old man with tetralogy of Fallot and cyanosis had a brain abscess in which *P. agglomerans* organisms grew in pure culture.¹¹⁰ Presenting manifestations included headaches, seizures, and left-sided weakness, which occurred over a 2-week period before admission. The patient recovered after undergoing drainage of the abscess and gentamicin therapy. A woman developed *P. calida* meningitis after surgical resection of a pituitary adenoma.³⁵ Several cases of peritonitis in patients on continuous ambulatory peritoneal dialysis have been reported^{33,54,65}; in one case the infection was thought to be secondary to a rose thorn injury.⁶¹

Diagnosis

Difficulty in identifying this organism is common; in March 1972, as part of a quality control program, *P. agglomerans* was sent as an unknown organism to 250 US hospitals and was identified incorrectly 45% of the time.⁶⁷ Even when fully identified in isolates from human sources, *P. agglomerans* often is considered a contaminant or saprophyte. The

organisms have been identified mistakenly as *Citrobacter*, *Escherichia coli*, *Flavobacterium*, and *Klebsiella*. In addition to routine microbiologic studies, identification of yellow-pigmented colonies and observation of the characteristic spindle-shaped bodies and symplasmata can aid in this differentiation.

MALDI-ToF and 16srRNA sequencing is reliable if species identification is required. Prognosis may not be much different, however, in patients said to have “*P. agglomerans*” bacteremia by conventional culture results, regardless of what genus and species is ultimately identified.¹⁷

Treatment

Most localized infections respond to treatment that includes an aminoglycoside. The presence of persistent localized infection with this organism should prompt a search for an organic foreign body, given the organism's tendency to live as a saprophyte or as a pathogen in vegetable material. In addition to appropriate antimicrobial therapy, treatment of bacteremia should include removal of any potentially contaminated intravenous access. The physician should be alert to the possibility of a common source of infection in nosocomial outbreaks.⁶⁷ In view of the rarity of bacteremia caused by *P. agglomerans*, single sporadic cases should be investigated, and clusters of two or more cases should lead to immediate inquiry into possible sources of contamination. In catheter-related infections, successful treatment did not always require catheter removal.¹⁷ Formal surveillance programs have been the key to early recognition and abortion of epidemics.⁶⁷

Acknowledgments

I thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

Aeromonas spp. were recognized for their role in disease first by Sanarelli in 1891. His findings associated aeromonads with bacteremic “red leg” disease in frogs.¹⁶⁸ Studies by Hill and associates in 1954 linked the first human disease, acute fulminating metastatic myositis, with *Aeromonas* infection.³² Generally *Aeromonas* spp. have been considered opportunistic pathogens for humans; however these organisms have been identified with increasing frequency as primary pathogens in normal individuals as well as in compromised hosts.

Aeromonas bacteria are ubiquitous. They are found as normal flora in nonfecal sewage and are isolated from tap water, canals, streams, and rivers. They also have been isolated from clinical and food samples. Aeromonads are pathogens for cold-blooded animals (fish, shellfish, amphibians, and reptiles) as well as commensal organisms of leeches.

EPIDEMIOLOGY

Ewing and associates⁶⁴ and other investigators have isolated *Aeromonas* from tap water and from the water or sediments of rivers, especially during periods when the water temperature was relatively warm.^{99,126,175} Hazen and colleagues⁸⁵ recovered *A. hydrophila* from 135 of 147 natural water sources in 30 states of the United States and reported that its density was higher in flowing (lotic) than in calm (lentic) water systems and lower in freshwater than in saline systems; *Aeromonas* could not be recovered from waters in which the saline content approached that of seawater or from extremely polluted waters. Leclerc and Buttiaux¹⁰⁹ found *Aeromonas* in 30% of more than 9000 samples of drinking water in France. Drinking water sampling by the US Environmental Protection Agency (EPA) in 2011 revealed the presence of aeromonads in 42 of 293 (14.3%) samples of public water systems in the United States.⁵⁷ *Aeromonas* spp. also have been recovered from hospital water supplies.^{126,149,150} Pin and colleagues¹⁵² isolated these organisms from clinical and food samples, including poultry, shellfish, pork, and beef, where they thrived even at low temperatures.

Aeromonas organisms survive readily on surfaces such as bench tops and moistened paper towels. Slotnick¹⁸³ recovered *Aeromonas* organisms from a moistened paper towel that had been allowed to dry 24 hours after the application of the organisms. When the towel was placed in a humidified closed environment, the period was extended to 2 weeks.

A. hydrophila may be found in the mouths of fish, alligators, turtles, tadpoles, and frogs.⁸⁹ Importantly *Aeromonas hydrophila* is a commensal organism in the digestive tract of leeches, required for the digestion of blood. This was originally found in 1983 when the practice of using leeches to control venous congestion after surgery began to rise in prominence. This form of leech therapy has now expanded to the pediatric population, which has resulted in cases of *Aeromonas* skin and soft tissue “flap” infection (see Clinical Manifestations).^{49,73,201} Studies done in Thailand and Turkey have found high percentages of *Aeromonas* in uncooked commercially sold seafood (27% of samples from Thailand, 94% of fish from Turkey).^{202,206} Another investigation of fish and animal meats bought at markets in northern India revealed *Aeromonas* species in 38 of 332 (11%) food samples.¹⁸⁰ It also has been found in the feces of guinea pigs and laboratory mice.⁵⁵ Unusual sources of *Aeromonas* infection include contamination of home or hospital hemodialysis equipment,^{94,158} tsunami-associated wound contamination,⁸⁸ and contamination of blood or blood products.^{154,159} San Joaquin and colleagues¹⁷⁰ noted that *Aeromonas* organisms also have been found in ornamental aquaria belonging to patients with *Aeromonas*-associated gastroenteritis; however they found that isolates from the aquaria differed in susceptibility testing from the gastrointestinal isolates, so the aquaria probably were not the sources of infection. A multicenter study of more

than 150 extraintestinal clinical isolates showed the presence of 22 isolates of *A. aquariorum*, a species once believed to be only virulent to ornamental aquaria.⁶⁷

Aeromonas also have been isolated from a large proportion of ready-to-eat salads.¹²² Of *Aeromonas* salad isolates, 35% were *A. hydrophila* or *A. sobria*. All isolates tested in this study had at least one marker of enteropathogenicity, including hemolysin and cytotoxin production. Nonetheless, few if any cases of diarrhea have been associated with ingestion of these salads in immunocompetent hosts.

In 1988, California made infection by *Aeromonas* a reportable condition, permitting the first population-based study of the epidemiology of infection caused by this organism. The overall incidence rate for *Aeromonas* isolation was 10.6 cases per 1 million population. The gastrointestinal tract was the most common site of infection (81% of cases), followed by wounds (9%). Five (2%) of 219 patients with *Aeromonas* infection died; all had serious underlying medical conditions.¹⁰³ Studies of traveler's diarrhea revealed the presence of *Aeromonas* spp. in eight of 56 (14%) stool samples in Thailand.⁴¹ A retrospective review of diarrhea in neonates in Bangladesh showed the presence of *Aeromonas* spp. in 222 of 699 stool samples that were positive for bacteria (222 of 2511 overall), making it the second most common isolate after *Vibrio cholerae* in this cohort.¹⁰² A study involving patients with diarrhea in Spain showed *Aeromonas* spp. in 32 of 800 (4%) diarrheal stools.¹⁴³ The bacteria isolated were found to be similar (by pulsed-field gel analysis) to isolates from drinking water isolates. Data from a study in southern Brazil using 680 stool samples from patients with diarrhea compared with 300 healthy controls showed that 2.6% of the diarrheal samples contained *Aeromonas*, whereas only 0.3% of the control samples contained this organism.¹⁸⁹ *A. hydrophila* has been placed on the EPA's contaminant candidate list of emerging pathogens in drinking water because it has the potential to grow in water distribution systems and to be resistant to chlorination.²³

ETIOLOGIC AGENT

Aeromonas organisms are motile, asporogenic, gram-negative rods that contain a single polar flagellum. The organisms are oxidase positive and catalase positive and produce acid or gas during carbohydrate fermentation. They can grow at temperatures between 0°C and 41°C. Growth may occur within a pH range of 5.5 to 9. Lipase, gelatinase, DNase, and other exoenzymes are formed by these organisms.^{63,174,198}

Aeromonads grow well on blood agar; most strains produce a large zone of β -hemolysis on this medium, although nonhemolytic strains exist. *Aeromonas* colonies on blood agar have a ground-glass appearance and a fruity odor.²⁰⁰ Aeromonads also grow on MacConkey, eosin-methylene blue, *Salmonella-Shigella*, and triple-sugar iron media.

The sensitivity and specificity of various media for detection of *Aeromonas* spp. in fecal specimens have been evaluated.^{7,136,164,197} Isolation is achieved readily on any of the following: Pril-xylose-ampicillin agar, xylose-sodium, deoxycholate citrate agar, alkaline peptonic water, inositol-brilliant green bile salts agar, trypticase soy broth with ampicillin, and dextrin-fuchsin-sulfite agar.¹⁹⁷ The colonies appear almost colorless on these media, with the exception of growth on dextrin-fuchsin-sulfite agar, on which they appear dark red.

Mishra and associates¹³⁰ evaluated five selective agars. Of these, sheep blood agar with 30 mg of ampicillin per liter (ASBA 30) permitted the greatest number of *Aeromonas* colonies to grow while also inhibiting the competing fecal flora. These researchers recommend that ASBA 30 be used with DNase-toluidine blue agar (DNTA) to detect the ampicillin-susceptible strains and the nonhemolytic strains. The combination of ASBA 30 and DNTA allowed 98% of all isolates to be detected.

Strains of motile *Aeromonas* isolates can be identified to species level by use of the following tests: production of nitrate reductase; fermentation of D-glucose and trehalose; failure to use mucate; and the inability to produce acid from D-arabitol, dulcitol, erythritol, and xylose.¹ More recently, the use of restriction fragment length polymorphism analysis of the 16S rRNA, along with gene sequencing of common genes has contributed to the identification and speciation of *Aeromonas* isolates.^{67,156} Detection of *Aeromonas* organisms by use of strain-specific fluorescent antibody has been described.¹⁹⁷ The technique is not satisfactory; only a small percentage of isolates react with prepared antisera, which suggests the presence of numerous serogroups. The use of a monoclonal antibody against *A. hydrophila* has been shown to overcome this problem however.³³ This monoclonal antibody could prove beneficial in the future as a screening tool. Additionally the study of selected housekeeping genes has been helpful in establishing phylogenetic relationships among members of the aeromonads.¹⁸⁶

Aeromonas previously was considered a member of the Vibrionaceae, which included the genera *Vibrio* and *Plesiomonas*.¹⁵⁵ Molecular genetic techniques have identified that these three genera are not related evolutionarily, however, and aeromonads represent a family of their own.⁴⁸ Genome sequencing has further added to the growing knowledge of *Aeromonas* taxonomy and has also given great insight into the diversity of virulence factors, such as quorum sensing and biofilm formation.^{16,36,37,39,47,132,191} *Aeromonas* have long been viewed as belonging to one of two major groups on the basis of their ability to grow at different temperatures. Mesophiles were strains that grew at 35°C to 37°C, and psychrophilic strains were more prevalent at lower temperatures (22°C–28°C). These two groups could be distinguished not only by optimal growth conditions but also by elaboration of pigmentation on tyrosine agar and production of indole. The mesophilic strains are motile, and the psychrophilic strains are nonmotile.

Twenty-two *Aeromonas* spp. have been recognized, and this number is expected to increase as new strains are isolated and identified.^{1,146} Although the number of strains of psychrophilic *Aeromonas* spp. has remained stable, the number of various strains of mesophilic species isolated has increased. Several classification schemes within the genus are in use. The strains are classified based on biochemical assays or the use of genotyping techniques such as DNA-DNA hybridization and restriction fragment length polymorphism of the 16S rRNA, or both. Genetic techniques have been used to differentiate the genus into genomospecies or hybridization groups (HG), allowing more precise identification.²⁴

Abbott and associates¹ classified *Aeromonas* based on the results of the Møeller decarboxylase and dihydrolase reactions. They also were able to place the strains they studied into complexes based on certain biochemical reactions. The *Aeromonas* strains that produced elastase, pectinase, and stapholysin were grouped into the *A. hydrophila* complex (*A. hydrophila*, *A. bestiarum*, and *A. salmonicida*). Similarly the *A. caviae* complex includes *A. caviae*, *A. media*, and *A. eucrenophil*. The *A. sobria* complex comprises *A. veronii* HG8, *A. jandaei*, *A. schubertii*, and *A. trota*.

In addition, other species, including *A. media* (similar to *A. salmonicida*),⁸ *A. veronii*,⁸⁷ *A. schubertii*,^{31,86} *A. jandaei*,³⁰ *A. trota*,²⁹ *A. allosaccharophila*,¹²⁰ *A. encheleia*,⁶² *A. bestiarum*,¹⁰ *A. popoffii*,⁹² and *A. eucrenophil*,¹⁷⁴ have been described. A new species, *A. culicicola*, was isolated more recently.¹⁵¹ Other isolates include *A. enteropelogenes* and *A. ichthiosmia*, which seem to be similar to previously identified species.⁴⁶ Of the species isolated currently, *A. hydrophila*, *A. caviae*, and *A. veronii* have been associated most often with human infections.¹²⁸

Aeromonas is confused most frequently with Enterobacteriaceae. The oxidase test always should be performed to aid in differentiation; *Aeromonas* organisms generally are oxidase positive, whereas the Enterobacteriaceae are oxidase negative. McGrath and associates¹²⁴ described oxidase-variable strains of *A. hydrophila*. These strains are oxidase positive when grown on nonselective media but oxidase negative when grown on differential or gram-negative media. Organic acid end-products of lactose fermentation can inhibit the oxidase reaction. Paik¹⁴⁴ also has shown that a platinum wire loop should be used for oxidase testing; use of an iron-containing loop can cause false-positive oxidase results.

Although drug resistance is a rapidly emerging concern, *Aeromonas* has traditionally shown susceptibility to ceftriaxone (8 µg/mL), chloramphenicol (2–4 µg/mL), gentamicin (0.5–2 µg/mL), streptomycin (16 µg/mL), trimethoprim-sulfamethoxazole (<0.5–9.5 µg/mL), and imipenem and meropenem.^{14,64,65,141,142,161,197} Reinhardt and George¹⁶² determined that the most active on a weight basis were ciprofloxacin, enoxacin, and norfloxacin; nalidixic acid and trimethoprim-sulfamethoxazole also possessed good activity. Neither sulfamethoxazole nor trimethoprim alone was active. In addition, these investigators did not note appreciable differences in susceptibility among species or in susceptibility between fecal versus nonenteric isolates. In contrast, Motyl and colleagues¹³⁵ noted higher levels of resistance to various antibiotics among *A. hydrophila* strains compared with *A. sobria* or *A. caviae*, as judged by minimal inhibitory concentration. Susceptibility to cephalothin may serve as a useful criterion in the identification of *A. sobria*.^{135,170} Resistance to fluoroquinolones has been shown to be based on chromosomal mutations of the *gyrA* and *parC* genes,^{2,9,73} along with a plasmid containing a *qnrS* gene^{11,12,84} and a separate plasmid with the *aac(6′)-Ib-cr*.⁶⁶

Aeromonas organisms consistently are resistant to penicillin, ampicillin, carbenicillin, cephalothin, erythromycin, clindamycin, and vancomycin. Sawai and associates¹⁷³ showed that resistance to β-lactam antibiotics is caused by the production of a species-specific, chromosome-mediated β-lactamase. Two studies of *Aeromonas* spp. cultures examining for the presence of the *cphA* gene encoding for metallo-β-lactamase have been published. In Brazil, 87 *Aeromonas* isolates recovered from environmental sources showed a prevalence of the *cphA* gene in 97.6% of *A. hydrophila* isolates and 100% of *A. jandaei* isolates. Likewise, 51 consecutive blood isolates of *Aeromonas* spp. were examined; it was found that, overall, *cphA* was present in 69% of these isolates. The rise of these resistant strains of *Aeromonas* spp. is very troubling.^{14,61,118,203} Multidrug-resistant *Aeromonas* have been recovered both in the stool of children with gastroenteritis, as well as in environmental samples.^{61,118,14,203} Tetracycline resistance was found in environmental and fish isolates of *Aeromonas* by Han and colleagues.⁸³ This resistance was conferred by several *tetA* through *tetE* genes; *tetE* was found on a plasmid. It is not R plasmid-mediated. In 1980, McNicol and coworkers¹²⁵ reported the recovery of *Aeromonas* isolates from the Chesapeake Bay that were resistant to tetracycline and polymyxin B. They also noted that 57% of isolates from Bangladesh had a multiple streptomycin-chloramphenicol-tetracycline resistance phenotype that correlated with the presence of a larger plasmid. Extended-spectrum β-lactamase (ESBL)-producing *Aeromonas* infections are also becoming more prevalent. A report from Taiwan highlighted the presence of ESBL-producing isolates from 4 of 156 patients with *Aeromonas* bloodstream infection. Resistance was encoded by bla(TEM), bla(CTX-M), and bla(SHV) genes, and conferred resistance to cefotaxime, ceftazidime, and cefepime.²⁰⁴

PATHOGENESIS

In addition to its pili, *A. hydrophila* produces numerous virulence factors, including extracellular toxins and enzymes that are involved in the pathogenesis of *A. hydrophila* infection. Some of the toxins elaborated by *A. hydrophila* include hemolysins, aerolysin, and enterotoxins.^{18,72,156,160,176}

Like many other gram-negative bacteria, *Aeromonas* spp. employ a type III secretion system to bind to host cells and deliver toxins.² *Aeromonas* spp. have also been found to produce quorum-sensing molecules which control the expression of many virulence determinants.^{36,37,39,190,191}

α-Hemolysin is released from cells during a stationary growth phase. It has a molecular weight of 50^{113,114} to 65¹¹⁴ kDa and is stable at room temperature between pH 3.5 and 9.5. It is heat labile and is cytotoxic to HeLa cells and human embryonic lung fibroblasts.¹⁹⁶ When injected into rabbit skin, it causes dermonecrosis. Intraperitoneal injection of α-hemolysin is lethal for rabbits and mice.

β-Hemolysin has a molecular weight of 49 to 53 kDa and is released near the end of the logarithmic phase of growth of the *Aeromonas* organism. It is heat labile and resists destruction by trypsin and pronase.¹¹⁴ It causes dermonecrosis of rabbit skin and is lethal for rabbits, rats, and mice. It is cytotoxic to HeLa cells and to human diploid lung fibroblasts.¹⁹⁴ It also has been shown to induce impairment in the intestinal epithelial

barrier and to stimulate active chloride secretion in human colon cell monolayers, contributing to enteritis.⁶⁰

α -Hemolysin and β -hemolysin may be significant virulence factors. Most clinical isolates are β -hemolytic, and hemolysis is a common feature of infection caused by *Aeromonas* spp. α -Hemolysin and β -hemolysin in high concentrations produce hemorrhagic enteritis in a rabbit ileal loop; however neither is clearly established as a virulence factor in diarrheal disease.¹¹⁵ Antibodies to either hemolysin neutralize both toxins.

Aerolysin is a pore-forming toxin that shares some homology with β -hemolysin.⁶⁰ After inserting into its target cells, it disrupts ion gradients and membrane potentials, leading to cell lysis.¹⁰⁸ Caco-2 cells derived from human intestine have been shown to be very sensitive to the effects of aerolysin.⁴

In 1975, Sanyal and associates¹⁷¹ showed that the enterotoxins from *A. hydrophila* were enterotoxigenic. Subsequently, enterotoxigenic *A. hydrophila* has been isolated from humans,^{28,76-79,99,199} water sources,¹⁸ fish, and pigs.^{25,141} Sha and colleagues¹⁷⁷ have characterized three enterotoxins from *A. hydrophila*. The cytotoxic enterotoxin has hemolytic, cytotoxic, and enterotoxic activities and has a molecular weight of 52 kDa. It is a pore-forming toxin that has been shown to cause fluid secretion and tissue damage in mouse ileal loops.¹⁰⁸ The other two are cytotoxic enterotoxins. One has a molecular weight of 44 kDa and is heat labile. The second has a predicted molecular weight of 71 kDa and is heat stable. These cytotoxic enterotoxins cause elevation of cyclic adenosine monophosphate and prostaglandin levels in Chinese hamster ovary cells and fluid secretion in rabbit ileal loops.¹⁷⁷ All three enterotoxins have been implicated in *A. hydrophila*-induced gastroenteritis. *Aeromonas* spp. also produce proteinase A and B, endopeptidase, staphylolytic enzyme, fibrinolysin, and leukocidin.¹¹³ The precise relationship of these toxins and enzymes to the pathogenesis of human infection is unclear.

Strains of *Aeromonas* produce proteases, DNase, lecithinase, and elastase.⁵ These extracellular enzymes may have pathologic significance. *Aeromonas* strains that possess hemolytic and cytotoxic capabilities and that are characterized as HG1/BD-2 type strains have been related strongly to patients with diarrheal disease.¹⁰⁶ Human *Aeromonas* isolates have been found also to express Shiga toxins (much like Shiga toxin-producing *Escherichia coli*).¹¹

Antihemolysin and agglutinating and precipitating antibodies to *A. hydrophila* have been detected in patients with systemic *Aeromonas* infections but not in patients with superficial infections. Increases in the antihemolysin titer to 1:1280 and in the agglutinin titer to 1:640 have been noted.³³

Burke and colleagues²⁷ found that many strains associated with diarrhea were able to hemagglutinate cells from human, horse, rat, and guinea pig. Of these strains, 68% displayed fucose-resistant hemagglutination. The investigators suggested that these properties may contribute to virulence. The ability of *Aeromonas* spp. to create biofilm allowing for colony protection and quorum sensing has been demonstrated.^{38,58}

Ketover and associates¹⁰⁰ showed that normal serum promotes phagocytosis and intracellular killing of *Aeromonas* organisms by normal white blood cells. In contrast, sera from two patients with fatal *Aeromonas* infections failed to do so. One patient had an increase in the serum opsonic antibody titer from less than 1:5 in the acute stage of disease to 1:5120 in the convalescent stage. These studies suggest that a specific opsonizing antibody that is present in normal serum and normal bactericidal activity of neutrophils are required to prevent invasive *A. hydrophila* infections.

The flexible type IV pili of *Aeromonas* are the predominant pili expressed on fecal isolates of diarrhea-associated species of *Aeromonas*. They represent a family of type IV pili that has been designated as bundle-forming pili (Bfp). Kirov and associates¹⁰⁴ have presented compelling evidence to support the concept that Bfp are important intestinal colonization factors. More recently, this group also showed that *Aeromonas* flagella are adhesins for human intestinal cells, playing a role in its enteropathogenicity.

Serogroup analysis may be helpful in establishing which *Aeromonas* isolates can cause human disease. Serogroups O:11, O:34, and O:16 predominate as causes of clinical infection.⁹³ Hadi and colleagues

successfully isolated a 22-kb region of the *A. veronii* bv. *sobria* genome, demonstrating many functions of the Bfp subunits by mutations.⁸²

Clear correlation between known virulence properties and enteropathogenicity in humans is lacking. This lack of a clear correlation has been attributed to the heterogeneity of *Aeromonas* spp., the great variety of *Aeromonas* virulence factors, and the loose association between virulence factors and the phenotype and genotype.¹²⁸ Consequently many researchers have proposed a multifactorial pathogenesis with the involvement of numerous cellular and extracellular virulence factors.⁴²

CLINICAL MANIFESTATIONS

Aeromonas spp. have been implicated as a cause of septicemia, gastroenteritis, peritonitis, skin and wound infections, osteomyelitis, septic arthritis, ocular infections, myositis, urinary tract infections, pneumonia, meningitis, and hemolytic-uremic syndrome in children. Infections have been noted in normal and immunocompromised hosts.^{17,22,68,147,148}

Sepsis caused by *Aeromonas* spp. has been reported in children.* Because *Aeromonas* infection is not a reportable disease, the total number of affected children is unknown. Although septicemia caused by *Aeromonas* spp. has occurred in normal children, most children affected have had a disorder known to impair the normal host response to infection or a disorder in which the intact skin as a barrier to infection has been destroyed. *Aeromonas* infection has been noted in children with leukemia (particularly those with neutropenia), aplastic anemia, cirrhosis, hemoglobinopathies, malnutrition, burns, and renal failure. Neonates are susceptible to sepsis when exposed to contaminated water. Chaudhari and Todd detailed neonatal sepsis, necrotizing enterocolitis, and death associated with *A. hydrophila* in a 27-week-gestation neonate born in a toilet.⁴⁰

The clinical manifestations of septicemia are similar to the manifestations noted in other gram-negative enteric bloodstream infections with high fever and shock. During the course of septicemia in some of these patients, ecthyma gangrenosum also has been noted. The reported case-fatality rate of 50% despite administration of antibiotic therapy presumably is related to the severity of the underlying disorders and not to an unusual virulence of the organism. The propensity for infection in the compromised host suggests that *Aeromonas* organisms are of low virulence for the human host. Bacteremia with *A. sobria*, *A. punctata*, *A. veronii*, *A. caviae*, and *A. schubertii* also has been described.^{43,94,98,159,182}

Meningitis caused by *Aeromonas* spp. also has been reported in children.^{69,70,205} In one reported review of 21 years' experience with gram-negative bacillary meningitis, *Aeromonas* spp. accounted for 2% of the cases.¹⁹⁶ The course was fulminant, and the patients died despite having received antibiotic therapy. All of these children could be considered immunocompromised as a result of sickle-cell anemia (a 23-month-old child) or age (neonates).

Gastrointestinal infections caused by *Aeromonas* spp. have been reported with greater frequency in pediatric patients. *A. hydrophila*, *A. sobria*, *A. caviae*, and *A. punctata* have been recovered from stool specimens of patients with gastroenteritis.^{28,35,71,94,134} In 1961, Martinez-Silva and colleagues¹²¹ described an epidemic of enteritis in a newborn nursery affecting nine infants (eight as neonates and one at 7 days old). *Aeromonas* spp. were found in the stools of six of these infants. One neonate, the only patient with a pure growth of *Aeromonas* in a stool specimen, died. In 1964, Rosner¹⁶⁶ reported severe gastroenteritis in a child with growth of *A. hydrophila* from four stool cultures. In 1991, one study reported 224 cases of *Aeromonas* gastroenteritis in Iowa from January to June.¹⁵⁷ Taneja and associates¹⁹² described an outbreak of diarrhea caused by *Aeromonas* spp. on a hematology-oncology ward in a pediatric hospital during March/April 2001, where six of 18 children were infected. *Aeromonas* spp. were found to be the sole enteropathogen in five of the six children. *Aeromonads* have been detected worldwide as the sole pathogen causing diarrhea in 2% to 20% of affected children and in only up to 2% of children without diarrhea.^{42,54,79,193}

In an attempt to assess the role of *Aeromonas* spp. in diarrheal disease, numerous investigators have evaluated the fecal carriage rate of the

*References 26, 45, 51, 80, 91, 100, 138, 147, 165, 172, 200, 205, 207.

organism.⁸¹ Freij⁷⁰ described a study performed by other investigators who recovered *Aeromonas* from none of 300 adults and from 31 of 4426 (0.7%) children younger than 2 years. Pitarangsi and coworkers¹⁵³ reported carrier rates of 16% to 27% in various districts in Thailand and noted the same frequency of *A. hydrophila* in stools of Thais with and without diarrhea. In contrast, *A. hydrophila* was recovered from the stools of American Peace Corps volunteers more frequently when they had diarrhea than when their stool frequency was normal.⁴¹ Only three *Aeromonas* isolates were reported from 1685 rectal swab cultures obtained from 1217 children hospitalized for gastroenteritis in Manitoba, Canada. Bhat and colleagues¹⁹ recovered *Aeromonas* organisms from seven of 133 patients with acute diarrhea in a valley in India and found *Aeromonas* and *Plesiomonas shigelloides* in the well water commonly used by these individuals. Soltan Dallal and Moezardalan¹⁸⁷ isolated *Aeromonas* spp. from 14 of 310 Iranian children in a case-control study. A large, retrospective study on the island of Crete found the prevalence of *A. hydrophila* to be 0.44% in submitted stool cultures from children over an 18-year period.¹¹⁹

Gracey and associates^{77,78} described a prospective study in Australia of 1156 children with diarrhea and an equal number of age- and sex-matched control subjects. Enterotoxigenic *Aeromonas* organisms were isolated from 10.2% of children with diarrhea compared with 0.6% of healthy children. *Aeromonas* was the only potential pathogen recovered in 6.5% of children with diarrhea. Cases of *Aeromonas* infection peaked during the summer months. The mean duration of diarrhea was 15.3 days, and 33% of the children required hospitalization. These investigators described three clinical syndromes of *Aeromonas* gastroenteritis: (1) watery diarrhea, vomiting, and low-grade fever in 41%; (2) diarrhea with blood and mucus in 22%; and (3) prolonged diarrhea of more than 2 weeks' duration in 37%.

Many investigators^{6,34,137,139,169} have attempted to describe gastrointestinal infections caused by *Aeromonas* spp. Gluskin and associates⁷⁴ performed a 15-year study of the rate of *Aeromonas* spp. in gastroenteritis in hospitalized children. A total of 146 strains of *Aeromonas* spp. were isolated from 32,810 fecal specimens from 13,820 hospitalized patients. These isolates constituted 4% of all pathogenic bacterial strains cultured. Most of the cases of diarrhea (94%) occurred in children younger than 3 years. The peak incidence occurred in infants aged 2 to 6 months. Bloody diarrhea occurred in 7% of children. Several investigators^{6,169} have detected a larger number of cases of *Aeromonas*-associated diarrhea in the summer months than in other months, whereas Challapali and colleagues³⁴ found no seasonal patterns of *Aeromonas* isolation. The greatest number of cases occurred in children younger than 12 months to 3 years of age.

Symptoms included diarrhea, bloody stools, vomiting, abdominal cramps, mild dehydration, and fever. *Aeromonas*-associated diarrhea resembled other types of bacterial diarrhea, except that fecal leukocytes were absent in children with *Aeromonas*-associated diarrhea; in contrast, fecal leukocytes were found in 60% of children with other types of bacterial enteritis.³⁴ A cholera-like illness caused by enterotoxigenic *A. sobria* has been described.^{35,107} Gastroenteritis caused by *A. sobria* and *A. hydrophila* tended to be acute, whereas diarrhea associated with *A. caviae* frequently was chronic, lasting 4 to 6 weeks in untreated patients.

San Joaquin and Pickett¹⁶⁹ described three patients with *A. caviae* diarrhea who originally presented with failure to thrive presumed to be secondary to formula intolerance. Diarrhea in these patients improved after administration of trimethoprim-sulfamethoxazole. Moyer¹³⁷ noted that although *A. caviae* is considered nonpathogenic, five pediatric patients with otitis media who were treated with penicillin or ampicillin subsequently developed diarrhea in which *A. caviae* was the only potential enteric pathogen. The prior therapy with antibiotics to which *Aeromonas* spp. are known to be resistant probably contributed to colonization of the gastrointestinal tract with *A. caviae* and subsequent development of diarrhea. These four patients also were treated successfully with trimethoprim-sulfamethoxazole.

Outbreaks of diarrhea associated with *Aeromonas* in daycare centers have been described.³⁴ *A. caviae*, *A. hydrophila*, and *A. sobria* were the strains recovered most commonly.

Complications of *Aeromonas* intestinal infection included gram-negative bacteremia, intussusception, internal hernia strangulation,

hemolytic-uremic syndrome,^{22,131,163} and failure to thrive. Peritonitis has been reported in a 5-year-old patient with a ruptured appendix.⁹¹ No additional clinical information about this patient was provided. Peritoneal dialysis catheter-related peritonitis was described in one patient.¹¹² The patient was involved in gardening and had poor adherence to peritoneal dialysis protocol and hand washing guidelines.

A. hydrophila has been recovered from the skin or from wound infections of children.* Most of these patients have been normal hosts; three had leukemia. In 40% of these cases, *Aeromonas* organisms were not recovered from the lesion in pure culture. The lower extremity was involved in 75% of these cases. Exposure to water was noted in 40% of these cases; alligator bites, snake bites, stepping on glass, and burns were other presumed predisposing factors. Clinical manifestations included cellulitis, hemorrhagic blebs, and purulent diarrhea with fever and leukocytosis. Secondary bacteremia and osteomyelitis have been reported.^{21,90} In a study of neonates with omphalitis in Karachi, Pakistan, 19 of 583 (3.2%) of purulent secretions from umbilical stumps yielded a positive culture with *Aeromonas* spp. The clinical implications of the presence of *Aeromonas* in these neonates was not discussed.¹²⁹

Aeromonas organisms have been recovered from skin lesions that have been the result of tick bites. In each of the cases, a circumscribed area of purple discoloration has surrounded the bite, and nonpurulent drainage from the center of the lesion yielded the organism. These patients sought medical attention because the local lesion had persisted or had increased in size over the course of 1 to 2 weeks. *A. schubertii* also has been isolated from traumatic wound infections.³¹

Ecthyma gangrenosum caused by *A. hydrophila* has been described in several children with leukemia.^{100,138,178} Ecthyma gangrenosum has been seen in several children with *Aeromonas* septicemia who have had malignant or hepatobiliary disease. Clark and Chenoweth⁴⁴ isolated *A. hydrophila* from an 18-month-old boy and a 2-year-old boy, both of whom had liver transplants for biliary atresia and subsequently developed cholangitis. In both instances, these were polymicrobial infections.

Current practice by plastic surgeons to use medicinal leeches to control venous congestion after reimplantation of limbs or closure of skin flaps has led to sepsis and skin and soft tissue infection with *Aeromonas* spp. in adults.¹¹¹ This practice is now becoming more prevalent in children, and practitioners should be aware that therapy with leeches requires antibiotic prophylaxis. Leeches can harbor *Aeromonas* spp. resistant to the prophylaxis of choice.

Lopez and associates¹¹⁶ described an 8-year-old child with acute myelogenous leukemia with bacteremia and osteomyelitis; *Aeromonas* organisms grew from a bone aspirate of this patient. Blatz²¹ reported finding osteomyelitis and *Aeromonas* bacteremia in a previously healthy 16-year-old patient; a bone aspirate was not attempted. Septic arthritis caused by *A. hydrophila* also has been described in a child with leukemia; the organism was recovered from the second metacarpophalangeal joint at autopsy.³¹ Elwitigala and colleagues⁵⁹ also recovered *A. hydrophila* in a previously healthy 13-year-old girl who developed severe septic arthritis of the knee after injury sustained in a private freshwater lake. This infection frequently is rapidly progressive.

Aeromonas has been recovered from the conjunctiva of a previously healthy 7-year-old boy whose eye had been penetrated by a safety pin¹⁸⁵ and from the anterior chamber of an 8-year-old boy who developed endophthalmitis after receiving a corneal laceration from a fishhook.⁴⁵ *A. sobria* endophthalmitis has been described in a 14-year-old patient after a penetrating eye injury occurred in which a cormorant pecked the patient's eye.¹¹⁰

Although numerous cases of *Aeromonas* urinary tract infections have been reported in adults, only a few cases have been reported in children. McCracken and Barkley¹²³ reported the recovery of *A. hydrophila* in pure culture from the urine of a 5-month-old boy with diarrhea. Bartolomé and colleagues¹⁵ described a case of urinary tract infection associated with diarrhea in a male neonate with bilateral ureterohydronephrosis and bladder involvement from posterior urethral valves. Ojeda-Vargas and associates¹⁴⁰ reported the case of an 18-year-old girl with severe pyelonephritis requiring admission to an intensive care unit: *A. hydrophila*

*References 15, 21, 52, 68, 91, 100, 123, 138, 148, 163, 178, 188, 197.

and *Pseudomonas* were isolated from her urine cultures. In a case series of seven patients with *Aeromonas* urinary tract infections in a hospital in Puducherry, India, one 4-year-old girl with chronic renal failure was found to grow *A. caviae* from a urine specimen.¹¹⁷

Myositis caused by *Aeromonas* also has been described in children. A 9-year-old girl and a 16-year-old boy required amputation of their legs as a result of *Aeromonas* myositis.^{52,184} Another case of sepsis accompanied by myositis of the thigh was described by Papadakis and associates in a 36-month-old girl with acute lymphoblastic leukemia; this child recovered well with prompt antibiotic therapy and surgical debridement.¹⁴⁵ Necrosis of muscle was noted in both cases, and gas was seen on the radiographs before amputation in the 9-year-old girl. Fatal myofascial necrosis also has been reported in a patient with a history of aplastic anemia.⁷⁵ *A. hydrophila* also has been isolated from abscesses caused by snake bites.⁹⁵

Pneumonia caused by *A. hydrophila* is a rare event in children. Kao and associates⁹⁷ reported that there have been a total of seven case reports in the literature so far, and four patients died of fulminant disease. Of the seven patients, four had accompanying medical conditions, including acute leukemia (two patients), cavernous hemangioma with thrombocytopenia (one patient), and nephrotic syndrome (one patient). One patient was the victim of a near-drowning, and two patients were previously healthy.^{97,161,181} One of the previously healthy patients was described by Kao and associates⁹⁷ in their case report and literature review. The patient was a 5-year-old girl who presented with fulminant sepsis and pneumonia and quickly died. *A. hydrophila* was recovered from her blood, endotracheal aspirate, and postmortem pleural fluid. Neither a bone marrow aspirate nor an immunologic workup was performed, so whether she had an underlying malignancy or immunodeficiency that might have contributed to her rapid demise is unknown. *A. hydrophila* has been isolated from lung abscess at autopsy of a 16-year-old girl with *A. hydrophila* septicemia and leukemia.⁵¹

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Aeromonas should be considered a possible cause of infection in children with any of the disorders previously noted. In addition, *Aeromonas* infection should be considered in any child noted to be exposed to a contaminated water source (e.g., sewage, waste). It also always should be included as a possible cause of gastroenteritis, bacteremia, and skin infection in a compromised host. Generally *Aeromonas* organisms are recognized only when they grow from body fluids or tissues that normally are sterile. Also, as noted earlier, *Aeromonas* infection should be suspected in ill children after the use of medicinal leech therapy in surgery or subsequent to an alligator, snake, or shark bite.³ The best methods for isolation of *Aeromonas* organisms have been described (see the section on *Etiologic Agents*).

A. hydrophila in food can be detected by an enzyme-linked immunosorbent assay and polymerase chain reaction.^{20,127,195} These organisms also have been identified in environmental samples by use of 16S rDNA-targeted oligonucleotide primers.⁵⁶ Many sophisticated techniques, including rRNA sequencing, DNA-DNA reassociation techniques, and polymerase chain reaction, have been used to continue to identify and differentiate *Aeromonas* spp.^{24,50,101,128}

TREATMENT AND PROGNOSIS

Penicillin-hydrolyzing β -lactamases have been detected in most strains of *Aeromonas*, rendering those strains resistant to ampicillin.¹³³ Piperacillin shows variable activity against *Aeromonas* spp., whereas ticarcillin-clavulanate generally is active. In vitro, *Aeromonas* organisms generally are susceptible to chloramphenicol, aminoglycosides, trimethoprim-sulfamethoxazole, aztreonam, quinolones, and the third-generation cephalosporins.^{96,105,167} Great care must be taken to obtain minimal inhibitory concentrations on *Aeromonas* isolates, and carbapenems should be initiated when there is lack of clinical response because ESBL-producing organisms are known to occur both in the environment

and in clinical isolates.¹⁴ Likewise, rates of tetracycline, fluoroquinolone, and aminoglycoside resistance should be known before considering these agents.^{2,12-14,84,179}

Initial empirical treatment with a third-generation cephalosporin is suggested. Following this, a drug to which the organism is sensitive should be provided (usually intravenously). The duration of administration depends on the site of infection and the clinical response to therapy. The occurrence of *Aeromonas* infections predominantly in compromised hosts accounts for the high case-fatality rate despite administration of an antibiotic agent to which the organism is susceptible.

In 1878, Kitt first isolated a bacterium of the *Pasteurella* group from wild hogs during an epidemic; 2 years later, Pasteur described the organism that causes fowl cholera. Since that time, the same organism has been implicated in rabbit septicemia, swine plague, hemorrhagic septicemia, and wildseuche (a fatal disease in deer). Hueppe applied the term *hemorrhagic septicemia* to this group of infectious diseases in lower animals because of the characteristic hemorrhagic areas seen scattered throughout the viscera. Original names for the causative organisms included *Pasteurella avisepctica*, *P. bovisepctica*, *P. suisepctica*, and *P. lepiseptica*, but these organisms now are classified under the name *P. multocida*, a small, nonmotile, gram-negative rod.⁵⁷

Although *P. multocida* was originally recognized as an animal pathogen, its role in human disease following animal exposure is now well established. Brugnattelli reported the first bacteriologically proven case in a human in 1913,¹⁰ and Hundeshagen described the first systemic human infection in 1919.³⁵ Schipper⁵⁸ did an extensive review of the literature from 1930 through 1947, and reported only 40 cases of infection with *P. multocida*. Since then an increasing number of human infections with *P. multocida* have been reported,⁶¹ and it has been recognized to be one of the primary pathogens implicated in wound infection and septicemia following bites from cats, dogs, and other mammals.^{50,64}

THE ORGANISM

P. multocida generally appears as a short, ovoid, gram-negative rod; however, it also may appear as a coccobacillus with convex sides and rounded ends. The length ranges from 0.3 to 1.25 μm , and the diameter ranges from 0.15 to 0.25 μm . *P. multocida* may appear singly or in pairs, chains, or clusters. Healthy organisms stain easily with aniline dyes and are gram negative. They may show bipolar staining, especially when smears are made directly from animal tissue or fluids. The organism becomes increasingly pleomorphic on subculture and may resemble Enterobacteriaceae in broth. They do not grow on eosin–methylene blue, MacConkey, deoxycholate, or any other bile-containing agar. They are facultatively anaerobic and nonmotile. They do not require X or V factor for growth, an important differential point in distinguishing *Pasteurella* species from *Haemophilus influenzae*. Its unique susceptibility to penicillin also differentiates it from other small gram-negative rods such as *H. influenzae*, a property noted in 1947 by Schipper.⁵⁸

Colonies are nonhemolytic and translucent, 1 to 2 mm in diameter, and generally, convex, and butyrous. Occasionally, they may be larger and mucoid or iridescent. Colonies on blood agar appear smaller, opaque, and grayish white. In broth culture, turbidity, often with flocculent sediment, is present.

Cultures tend to autoagglutinate in saline and have a peculiar musty odor. The organism is catalase positive and usually oxidase and indole positive. It usually ferments galactose, glucose, fructose, mannitol, mannose, and sucrose without production of gas. Some variability occurs in the fermentation of other sugars, and patterns of fermentation can be used to differentiate different strains of the organism.¹⁹ Using fermentation reactions, Oberhofer⁴⁹ developed a biotyping system in which correlation of biotype, 61% A and B, was found for cat-bite isolates but not with dog-bite isolates. *Pasteurella* reduces nitrates but has negative urease, methyl red, and Voges–Proskauer reactions. The pathogenicity of the organism varies; most mucoid and smooth colony-forming strains produce a capsule and usually are highly pathogenic for mice and rabbits. The capsule is antiphagocytic allowing the organism to resist intracellular killing by neutrophils, and each of the five capsular types (A, B, C, D, E, and F) is generally restricted to a specific host.

Nielsen and Rosdahl⁴⁷ developed a bacteriophage typing system for typing toxigenic and nontoxigenic strains. DNA hybridization studies

have led to a reclassification of the genus *Pasteurella*. *P. multocida* now includes three subspecies: *P. multocida* subsp. *multocida*, *P. multocida* subsp. *septica*, and *P. multocida* subsp. *gallicida*. Of 159 strains recovered from 46 infected humans, 95 were identified as *P. multocida* subsp. *multocida* and 21 were identified as *P. multocida* subsp. *septica*; the remainder were divided among multiple other species.²⁹ Other less common *Pasteurella* spp. include *P. canis*, *P. dagmatis*, and *P. stomatis*. The use of serology in conjunction with DNA fingerprinting can classify isolates for epidemiologic studies.⁷⁴

Polymerase chain reaction (PCR) analysis using universal primers for 16S rRNA genes, genomics, and molecular techniques are now the primary methods for identification, characterization, and differentiation of *P. multocida* and other Pasteurellae in research settings.⁷³

Immunity to *P. multocida* can be demonstrated in many animals, and animal vaccines have been developed with known efficacy, especially in birds and cattle.⁴ The precise mechanisms involved in the development of both vaccine immunity and, more importantly, natural immunity, are currently being elucidated. Antibodies to somatic and capsular antigenic determinants develop within 2 weeks of infection; with the capsular antibodies being longer lasting.¹² Woolcock and Collins⁷⁶ developed models in pathogen-free mice that may help uncover the mechanisms of immunologic protection. The efficacy of heat-killed vaccine is greatest when multiple doses are administered.

TRANSMISSION

Pasteurella is found in the oral flora of many different animals; 67% of cats may harbor this organism in their mouths or throats.⁷⁰ Smith⁶⁰ found that *P. multocida* could be recovered from the tonsils of 54% and from the nose of 10% of dogs. Schipper⁵⁸ grew *P. multocida* from 14% of wild rats trapped in the Baltimore area. Hansmann and Tully²⁸ showed that *P. multocida* can remain as a commensal for prolonged periods in the mouth of a cat. They described a patient who had been bitten on two occasions, 3 years apart, by the same healthy pet cat; each time, an abscess caused by *P. multocida* developed. *P. multocida* also has been isolated from panthers, komodo dragons, Tasmanian devils, buffalos, minks, pigs, and opossums.^{2,11,33,42} *Pasteurella* infection is of particular concern following bites from large cats such as lions, tigers, and cougars.⁷³

Although verifying the mode of transmission has been easiest when an infection has been related specifically to a pet or a farm animal, many cases of infection caused by *P. multocida* have been documented despite a negative history of animal exposure. Respiratory tract infection with this organism has been described in veterinarians, farmers, dairy workers, and individuals employed in locations where animal tissues are processed. A recent case series reported three life-threatening *P. multocida* respiratory tract infections associated with palliative pet care in the home.⁴⁵

The possibility of a reservoir of infection in humans with resultant interhuman transmission has been considered. In a study of veterinary students, Smith⁶⁰ described two of 71 with positive throat cultures for the organism. *Pasteurella* was present in 1 student for a few days and in the other for the full 4 months of the study; both patients were asymptomatic. Several other cases of isolation of the organism from the human respiratory tract, many without associated symptoms or known animal contact, have been reported.

Interhuman spread by nasopharyngeal excretions, feces, and urine may occur and the organism has been recovered from these sites. The female genital tract is another potential source, especially for cases of septicemia and meningitis that occur during pregnancy and in the newborn period.

Investigators of an outbreak in a chronic disease hospital showed that *P. multocida* was potentially viable on a towel for 24 hours. Although the source in this outbreak was not established, this finding may have implications for spread in other situations, particularly for pet owners.³⁶

EPIDEMIOLOGY

P. multocida has been isolated from humans in all areas of North America and Europe, with some reports coming from other areas. In the United States, it is not a reportable organism, so incidence and prevalence data are unavailable. Lee and Buhr⁴⁰ have cited a seasonal variation in the number of reported cases related to dog bites, with the highest incidence being in the fall and winter months, possibly related to increased nasal carriage in dogs during that period. Other investigators have found no seasonal differences.^{18,44}

No difference in attack rate has been found between the sexes. The attack rate is higher in individuals of both sexes in very young (birth to 4 years old) and in older (>55 years old) individuals.

PATHOGENESIS AND PATHOLOGY

Animal Infection

In animals the organism is typically a colonizer, but it may invade via mucous membranes in animals under stress. Highly virulent strains can invade and cause septicemia, characterized by high fever, cardiac weakness, toxemia, and early death. Organisms can be cultured from the blood; autopsy findings from the affected animal may be minimal or include petechial hemorrhages on mucosal and serosal surfaces and in various organs. Animals can also develop pneumonia with a serofibrinous exudate in the interlobular septa of the lungs, a hemorrhagic gastroenteritis, and subacute and chronic infections such as otitis media.⁷² The mechanisms by which these bacteria invade the mucosa and cause systemic disease continue to unfold. Key virulence factors are the capsule and lipopolysaccharide, with others still being identified.²⁹

Human Infection

The most common infection for humans is the result of direct inoculation following an animal bite or scratch resulting in skin and soft tissue infection. Invasive disease, including septicemia and meningitis, as well as chronic pulmonary infection are described in humans. The pathology and pathogenesis are similar to those of other organisms, particularly other gram-negative organisms. Pulmonary infection is most common at the extremes of age as well as in immunocompromised individuals. Increasing numbers of invasive infections due to *Pasteurella multocida* have been reported in recipients of solid organ transplants.¹³

CLINICAL MANIFESTATIONS

In humans, three major types of infections occur.⁷¹ In the most common type, local skin infection occurs after a cat bite or scratch, a dog bite, or, rarely, the bite of another animal. Many cases have also been associated with non-bite exposure, such as licking.²¹ Local skin infection that follows an animal bite or scratch has a rapid onset of symptoms, a rapidly progressive acute cellulitis typically within the first few hours of the incident, in contrast to infection caused by other organisms such as *Staphylococcus aureus*, where onset of symptoms is more typically delayed. The infection may be associated with generalized lymphatitis, local lymphadenitis, or both. A gray serous or sanguinopurulent discharge from the puncture sites may be noted at presentation, with surrounding soft tissue erythema and swelling. *Pasteurella* infection can also cause necrotizing fasciitis with similar pathophysiology to that caused by *Streptococcus pyogenes*. Puncture wounds can result in osteomyelitis or tenosynovitis if the injury is deep and penetrates these tissues. These deeper infections most often occur after bites from animals with sharp incisor teeth deposit the organism on or under the periosteum. These infections are most common following cat bites, but have been reported following puncture bites from other animals including dogs.

Signs of systemic toxicity, such as chills and fever, may be present and regional lymphadenopathy develops later. Less commonly, the

infection may be lower grade and more indolent.⁵⁵ Patients typically have elevated leukocyte count with left shift and elevated inflammatory markers. Lee and Buhr⁴⁰ found *P. multocida* to be the most common infecting organism in a report of 69 dog bites that had been cultured; 20 of the bites became grossly infected, and *P. multocida* was isolated from 10. Of 30 wounds that were sutured, 14 (47%) were infected with *P. multocida*. Talan et al.⁶⁴ found that *Pasteurella* spp. were the most commonly isolated organisms isolated from 107 cat and dog bite infections. It was isolated from 50% of dog bites and 75% cat bites, with the majority of infections being polymicrobial for both types of bite. Other unusual localized infections include chronic skin ulcers, secondary infection of a gouty joint, and infection of a compound fracture site and an amputation site.⁶⁷

The respiratory tract is the second most common location for *Pasteurella* infections, and, as with skin and soft tissue infections, *Pasteurella* is typically isolated along with other organisms in chronic pulmonary infections. Cases of bronchiectasis, pulmonary abscess, and empyema have been reported, usually in patients with underlying chronic pulmonary disease such as cystic fibrosis or bronchiectasis.^{1,6,27,38}

Disseminated infection is the third major clinical manifestation of *Pasteurella* infection and these are commonly associated with antecedent animal exposure.⁶⁵ Many of these cases have associated meningitis, many of which were mistaken for *Haemophilus influenzae* or *Neisseria meningitidis* infection because of the morphologic similarities among these organisms. In a review of the subject in 1967, Controni and Jones¹⁵ noted 14 confirmed cases of *Pasteurella* meningitis; 11 occurred in adults, and three occurred in children. Eight of the 14 patients had a history of accidental or surgical trauma. The mortality rate was 50%, but only five patients were treated with antibiotics. Evaluation of the cerebrospinal fluid showed white blood cell counts ranging from 580 to 5200/mm³, all with a predominance of polymorphonuclear leukocytes. More recently, Green and coworkers²⁵ reviewed 29 cases of *P. multocida* meningitis in adults.

The first reported neonate with *Pasteurella* meningitis died at 88 hours of age.⁷ The infant's mother had a fever in the postpartum period, but her pretreatment cultures were lost, so verification of the source was not possible.¹⁵ Since then, a case of *Pasteurella* chorioamnionitis associated with premature delivery and neonatal sepsis and death within 1.5 hours of delivery has been reported,⁶³ as has a case of a fatal outcome for both mother and fetus after the mother sustained a cat bite at 37 weeks' gestation, resulting in overwhelming sepsis, death, and fetal demise.³⁴ Several young infants with septicemia and meningitis due to *Pasteurella* survived without apparent sequelae after treatment with penicillin or ampicillin and gentamicin. Pizey⁵² reported infection in a 3-week-old infant with septic arthritis with no recognized animal contact. *P. multocida* infection may take a rapidly fatal course even in an older infant.^{58,66} Clapp and associates¹⁴ described two infants with invasive *Pasteurella* infection following nontraumatic facial licking by pets. In another report, in utero infection at 12 weeks' gestation was described, resulting in fetal death. In this case there was no known animal-related trauma, but the mother had both cats and dogs, and *Pasteurella* was isolated from gingival cultures of all animals in the home.⁶⁹ A neonate with meningitis and cervical spine osteomyelitis with full recovery has also been reported.^{31,32} Other neonatal infections, primarily sepsis and meningitis, have been described with similar incidental exposure, usually licking by a pet. Bacteremia caused by *P. multocida* with concomitant meningitis due to echovirus 9 was described in a 22-day-old with good outcome.³

Guét-Revillet et al.²⁶ described 6 neonates with *P. multocida* meningitis in France over a 10-year period and reviewed an additional 42 cases reported worldwide in infants less than 1 year of age. The majority of these infections followed nontraumatic animal exposures; there was a high rate of neurologic complications (37.5%), and 6 (14%) of the infants died. Siahianidou et al.⁵⁹ reported horizontal household transmission from a dog to a grandmother to a neonate causing sepsis and meningitis. In this case, the mother of the infant tested negative for colonization or infection.

More unusual invasive infections have also been reported in children and adults. Larsen and Holden³⁹ described a 14-year-old girl with chronic otitis media for 2 years who developed a *P. multocida* cerebellar

abscess. Nguefack et al.⁴⁶ described a case of a healthy 5-year-old boy with a large brain abscess caused by *P. multocida*, with the hypothesis that the infection was transmitted from a dog's saliva through an occult skull fracture. A healthy man developed endocarditis with no known animal exposure,⁹ and a case of epiglottitis caused by *P. multocida* has been reported in an adult.³⁷ A child developed Ludwig angina after non-bite exposure, and an adolescent boy with Kikuchi disease and *P. multocida* bacteremia has been described.⁷⁵ A 15-year-old boy with chronic lymphedema developed *P. multocida* bacteremic cellulitis of his penis and scrotum after local exposure to cat hair.⁸ In a report of 136 cases of non-bite-related *P. multocida* infections, the respiratory tract was the most commonly reported site, followed by the abdomen and genitourinary tract. The organism has also been recovered from patients with appendicitis, and it has been cultured from the female reproductive tract, urine, and from a chronic sacral abscess.^{5,34} Whether these cases were a result of ingestion of the organism or from hematogenous spread has not been determined. Raffi and colleagues⁵³ described three children with appendiceal peritonitis associated with *P. multocida*. The organism also has been isolated from infected peritoneal fluid in cases of peritoneal dialysis-associated peritonitis secondary to animal puncture of dialysis tubing^{41,43} and from the conjunctival secretions in an immunocompromised man with acute conjunctivitis after ocular exposure to his dog's respiratory secretions.¹⁶

Giordano et al.²⁰ described the clinical features and outcomes of 44 cases of *P. multocida* infection with and without animal bite exposure. This report concluded that infections associated with non-bite exposure more frequently occurred in immunocompromised patients or in those with comorbidities. Non-bite-associated infections in these patients more frequently resulted in bacteremia, longer length of hospital stay, and higher mortality rate.

DIAGNOSIS AND TREATMENT

Diagnosis of *P. multocida* infection is made definitively by culture. *Pasteurella* may resemble several other organisms morphologically, which may lead to initial misidentification, but identification is not difficult for an experienced microbiologist. The organism does not require X and V factors for growth, distinguishing it from *H. influenzae*. Its production of indole differentiates it from the *Neisseria* group and its inability to grow on MacConkey agar or a bile salt medium distinguishes it from *Acinetobacter* spp. and the enteric organisms. Multiplex PCR allows laboratories to differentiate *P. multocida* strains on the basis of the organism's LPS genotype.³⁰

The drug of choice for *P. multocida* infection is penicillin, to which the organism is exquisitely susceptible. This feature may be used to distinguish it from *H. influenzae* or the Enterobacteriaceae, organisms which are typically resistant to penicillin due to β -lactamase production. Rare strains of *P. multocida* that produce β -lactamase and are resistant to penicillins have been recovered.⁵⁶ The organism usually is sensitive to a wide variety of other antibiotics, including ampicillin, other broad-spectrum penicillins (e.g., piperacillin/tazobactam), amoxicillin/clavulanic acid,²² tetracyclines, parenteral cephalosporins (particularly second- and third-generation agents and ceftazoline fosamil),^{24,48} and chloramphenicol. Semisynthetic penicillins (e.g., nafcillin, dicloxacillin), erythromycin, some orally administered cephalosporins (cephalexin, cefaclor), and clindamycin (all antibiotics commonly used empirically for treatment of wound infections) have relatively low activity against *P. multocida*^{61,17,23} and may lead to failure of initial therapy if used alone to treat or provide prophylaxis for wound infections due to animal bites. Azithromycin seems to have acceptable activity,¹⁴ as does ciprofloxacin.³⁶ Trimethoprim-sulfamethoxazole is an acceptable alternative treatment, particularly for patients unable to take a β -lactam antibiotic,⁵⁷ but it will not provide adequate coverage for *Streptococcus pyogenes*, so must be used with in combination with another agent. Surgical drainage or debridement also may be necessary for areas of abscess or necrotic tissue. The duration of treatment depends on the primary disease process. Seven to 10 days generally is adequate for local infections, with longer courses indicated for meningitis and deeper infections, including those involving bones and joints.

PROGNOSIS AND PREVENTION

Proper cleansing and debridement of wounds caused by animal bites or scratches is important to prevent bacterial infection, including those caused by *P. multocida*. Lee and Buhr⁴⁰ found that suturing wounds caused by a dog bite was associated with a higher incidence of infection. Whether a wound is sutured often depends on the site and the potential cosmetic consequences of not suturing the wound. The use of prophylactic antibiotics following animal bites to prevent infection is guided by several factors. Most experts recommend their use for facial bites, those with delayed medical attention, for all cat bites and other deep puncture wounds, or for patients with immunocompromising conditions.⁶²

Choice of antibiotic for prophylaxis following a bite should include coverage for *P. multocida* in addition to other common organisms implicated in skin and soft tissue infection. Typically amoxicillin-clavulanate is effective, and guidelines are available for other treatment options for patients with drug allergies.⁶² Limiting contact with wild and domestic animals that may harbor the organism is probably the only definitive way to prevent infection. Teaching the proper handling of pets and keeping pets from licking infants and young children, as well as pregnant women, particularly on the face, may help.⁵¹ No vaccine for human use is currently available.

Prognosis of infection with *P. multocida* depends on the particular site of infection, the extent of infection, and the immune status of the host. With appropriate and timely treatment, resolution usually occurs, but the healing process may be slow, particularly for local infections with extension to the bone or tendons.^{18,68}

Cholera

117

Randy G. Mungwira • Matthew B. Laurens

Cholera is a toxin-mediated, secretory diarrheal illness caused by the bacteria *Vibrio cholerae*. Disease course varies from mild and self-limiting to severe and life-threatening. The most serious manifestation, *cholera gravis*, presents with rapid intravascular volume depletion and shock and can lead to death within 12 to 24 hours. The rapid progression to dehydration and explosive nature of outbreaks give reason for cholera to be one of the most feared public health threats. Cholera is also considered a disease of poverty because it disproportionately affects low-income countries.¹¹⁵ Epidemic, endemic, and a mixture of the two forms occur. Epidemic cholera typically occurs in populations with little preexisting immunity and affects both children and adults. Endemic cholera tends to affect children with a higher incidence and severity because of lower levels of acquired immunity relative to adults.³¹

Cholera incidence has increased since 2000.¹²⁹ In 2014, 42 countries, mostly in sub-Saharan Africa and Asia, reported 190,549 cases, 2231 deaths, and a 1.2% case-fatality rate.^{129,130} The United States reported seven cases in 2014, all imported.^{129,130} Cholera disease burden is considered vastly underreported, and the actual number of cases is estimated at 2.9 million annually (range, 1.3–4 million), with 95,000 deaths (range, 21,000–143,000 deaths).⁹² In recent times, outbreaks occurred in Tanzania, Malawi, Democratic Republic of Congo, the Republic of Congo, Cameroon, Chad, Niger, Iraq, Nigeria, Sudan, Somalia, Angola, Zimbabwe, and Haiti.^{126,131,134} In 2011, Haiti reported more than 500,000 cholera cases and 7000 deaths shortly after the October 2010 outbreak,⁷⁸ caused by a *V. cholerae* O1 variant similar to epidemic isolates from Southern Asia and Africa.⁴⁹ The case-fatality rate during the Haitian outbreak began at 7%, one of the highest recorded in recent history, and then fell to 1.3%, just slightly above the generally accepted benchmark of 1%.³³ Many organizations advocate for an integrated and comprehensive approach to control and prevention of this relatively neglected global public health problem.

HISTORY

Cholera has long been indigenous to the Ganges River Valley in northern India; however, the modern history of cholera is described in seven discrete pandemics, all originating from Asia and all presumably caused by the O1 serogroup.¹⁰ The first six pandemics, caused by the classic biotype, occurred between 1817 and 1923. The ongoing seventh pandemic began in Indonesia and South East Asia in 1961, and then spread throughout Asia and Africa. By 1991, it appeared in Peru and spread throughout Latin America. This most recent pandemic was caused by

the El Tor biotype, which has almost completely replaced the classic biotype and is the longest and most widespread of all pandemics to date.¹⁰ Several atypical El Tor variants containing phenotypic and genetic characteristics of the classic biotype have been identified, suggesting the emergence of hybrids.¹⁰³ In 1992, the first non-O1 serogroup isolated in association with an epidemic was reported.¹⁰² This new O139 Bengal serogroup emerged in India and Bangladesh, raising concern for an eighth pandemic, but it has not spread beyond the region to date. A novel strain of disease causing nontoxigenic O139 serogroup has recently been reported in Bangladesh.²⁶

The disastrous saga of cholera over the past 2 centuries helped shape public health as a discipline. Beginning in 1826, during the second cholera pandemic, many jurisdictions were induced to establish local sanitation and health boards, eventually evolving into the first organized public health apparatus. During the 1854 London cholera epidemic, investigations by Dr. John Snow demonstrated that disease transmission was associated with contaminated drinking water consumption from the city's infamous Broad Street pump; this episode is considered the first scientific public health investigation and gave rise to modern epidemiology.³⁹ In 1866, an epidemic in New York City led to the creation of the first Board of Health in the United States, and cholera became the first reportable disease.

The Italian scientist Fillipo Pacini identified the comma-shaped organism in 1854, but this discovery was overlooked until Robert Koch identified the cholera bacillus in 1883 during the fifth pandemic. Koch's cholera discoveries contributed to his pioneering work that began the field of Medical Microbiology.³⁹ The addition of glucose to enhance the absorption of sodium in oral rehydration therapy, the cornerstone of cholera treatment, has saved millions of lives and is heralded as one of the most important medical advancements of the 20th century.³⁹

MICROBIOLOGY

V. cholerae is a curved gram-negative rod classified by biochemical tests and subdivided into serogroups based on the somatic O antigen. It belongs to the family Vibrionaceae of Proteobacteria, which differs from the related family Enterobacteriaceae in being oxidase-positive and motile with a single flagellum. Vibrios are fermentative and oxidative in metabolism. They have few nutritional requirements and can grow in glucose as the sole carbon and energy source. Most vibrios are marine organisms, and most grow best in 2% to 3% sodium chloride under aerobic conditions. Although neither the typical comma shape of *V.*

cholerae nor its motility is seen on Gram stain, both are apparent in wet mount even on fresh fecal samples. If motility stops after adding anti-*Vibrio* antiserum, this establishes a presumptive diagnosis of the homologous organism.

Numerous *Vibrio* spp. exist, most of which are nonpathogenic in humans. *V. cholerae* spp. includes more than 200 serogroups classified according to the antigenic characteristics of the lipopolysaccharide O antigen.¹³ To date, only *V. cholerae* organisms carrying the somatic O antigens O1 and O139 are associated with epidemic disease. Some non-O1 *V. cholerae* serogroups cause sporadic diarrheal illness, which can be severe and sometimes invasive and inflammatory.

The O1 serogroup is divided further into two biotypes, classic and El Tor, based on biochemical properties and phage susceptibilities. The classic biotype traditionally causes a more severe disease, but the El Tor biotype may be better adapted to persist in the environment and establish epidemics. The classical biotype expresses genes conferring human virulence more than the El Tor biotype, which shows enhanced gene expression for biofilm formation, chemotaxis, and transport of amino acids, peptides, and iron.¹³ Classic and El Tor biotypes are divided into three serotypes (i.e., Ogawa, Inaba, and Hikojima) based on their dominant heat-stable lipopolysaccharide somatic antigens. The O139 serogroup comprises several genetically diverse strains, including nontoxic variants, and is genetically related to the O1 El Tor biotype.³⁵ Media used to isolate cholera organisms in stool include thiosulfate citrate bile salts sucrose (TCBS) agar and tellurite taurocholate gelatin agar. The appearance of yellow ("popcorn") colonies on TCBS agar is considered highly suggestive of *V. cholerae*. The bacterium is confirmed further by its ability to grow in the presence (or absence) of salt and by serology.

PATHOGENESIS

The pathogenic paradigm of *V. cholerae* comprises small bowel mucosa colonization followed by release of one or more enterotoxins, the most potent of which is the oligomeric cholera toxin itself. *V. cholerae* attaches to the intestinal mucosa by virtue of proteinaceous hairlike fimbriae, the most important being the toxin-coregulated pilus.¹⁰² These pili mediate microcolony formation of the intestinal epithelium. Colonization is facilitated by a protease that degrades mucin¹¹⁰ and epithelial tight junction-associated proteins and a single flagellum, which accelerates approach to the intestinal mucosa in conjunction with chemotactic receptors and intracellular sensor molecules.¹⁷

V. cholerae organisms shed in an infected individual's stool act more virulently than strains acquired from an environmental source. Serial passage through multiple patients may augment virulence further, partly accounting for the violent epidemics occurring throughout history.⁷⁷ On intestinal passage, genes required for acquiring nutrients and motility are upregulated, whereas genes required for chemotaxis are downregulated. This increased virulence was confirmed in an animal model in which *V. cholerae* shed by mice has a 10-fold lower infectious dose than organisms grown in vitro.⁷⁷ Reduced chemotaxis prevents dispersion in environmental waters and increases bacterial clumping¹⁸; the resulting increased concentration of organisms also may contribute to the vigor of cholera outbreaks.

Cholera toxin is composed of five identical binding (B) subunits and one active (A) subunit. Similar in structure and function to the heat-labile toxin produced by enterotoxigenic *Escherichia coli*,⁸³ cholera toxin binds to the GM₁ ganglioside receptor on the intestinal epithelial cell surface. The A subunit is internalized into the cell, where it activates adenylate cyclase by ADP-ribosylation of the G_{sa} protein. This results in cyclic adenosine monophosphate upregulation, causing an increase in chloride secretion from the intestinal crypt cells via the cystic fibrosis transmembrane conductance regulator chloride channel and a decrease in sodium chloride absorption by the villous cells. In addition to this mechanism, cholera toxin may have effects on prostaglandins and the enteric nervous system that could contribute to the voluminous diarrhea characteristic of the disease.⁶⁴ Water follows electrolyte loss along the osmotic gradient into the intestinal lumen. The dramatic fluid and electrolyte loss rapidly leads to decreased intravascular volume and to the complications of hypovolemic shock and metabolic acidosis. Although

cholera toxin is responsible for much of the pathogenicity associated with the organism, strains mutated in cholera toxin still elicit mild diarrhea.⁶⁴ Several other toxins have been identified, but their exact role in pathogenesis and immune modulation is not completely understood. These include the zonula occludens toxin, which increases small intestinal mucosa permeability through internal tight junction modulation, and the accessory cholera enterotoxin, an integral membrane protein thought to function as an ion-permeable pore.^{23,36,122} The multifunctional cholera toxin protein is also a powerful immunomodulator and may have potential applications in immunotherapeutics and as a mucosal or possibly epicutaneous adjuvant.^{14,90}

The genetics of *V. cholerae* provide insight into the organism's pathogenicity and spread. The genome of 4 million DNA base pairs comprises two circular chromosomes,^{32,51} the larger of which contains genes for growth and pathogenicity, and the smaller contains metabolism and regulation elements. The genes required for virulence can propagate laterally and among different strains. Required for pathogenicity are the cholera toxin genetic element and the *Vibrio* pathogenicity island, which encodes toxin-coregulated pilus and the critical regulator ToxT, the primary direct transcriptional virulence gene activator. The pathogenicity island can be moved between strains by phage transduction and chitin-induced transformation. Toxigenic strains emerge through the acquisition of the bacteriophage CTXΦ, which harbors the *ctxAB* gene encoding cholera toxin.⁷⁶ The complex regulatory system controlling virulence gene expression includes the ToxT/ToxR regulator proteins, quorum sensing, and small RNA molecule, and differs among in vivo and in vitro life stages^{16,53,76} and between clinical and environmental isolates.⁸⁰

EPIDEMIOLOGY

Cholera is classically described as a waterborne illness, but it can also be transmitted via contaminated food. The incubation period depends on the inoculum, with lower inocula corresponding to a longer incubation period and decreased stool volumes.⁶⁴ Incubation generally is 1 to 3 days, with a range of several hours to 5 days. Symptoms usually last 2 to 3 days, and patients treated with antibiotics may be infectious for several days. Patients who are untreated remain infectious for 1 to 2 weeks. Although waterborne transmission is typical in developing countries of Asia and Africa, *V. cholerae* found in marine environments can be transmitted via undercooked shellfish.³⁰ The role of household animals in transmission is probably minimal.¹⁰⁷ Person-to-person transmission was previously considered rare due to the high infectious dose,⁸⁴ but a recent study in Bangladesh documented up to 5% risk of household transmission during an 11-day infectious period compared to a 5% to 9% risk of infection over a 30-day period due to community-based exposure.¹¹¹ This investigation also documented increased susceptibility of children younger than 5 years compared to adults (odds ratio, 1.5–1.7).

Seasonal patterns in endemic areas have long been recognized for cholera outbreaks, with a predilection for warmer months. Studies conducted during interepidemic periods suggest a complex interaction between humans and the environment. *V. cholerae* exists in saline aquatic environments in a viable but nonculturable state, mostly in the form of metabolically dormant biofilm associated with zooplankton.^{55,116} This latent form originates from human stool, survives gastric acidity, and causes infection. When human cases begin to occur in a community, direct food and water contamination may occur, circumventing the need for the aquatic reservoir.³⁴ Seasonal epidemics are associated with other factors that affect the environmental reservoir, including changes in zooplankton blooms, chitin abundance, and rainfall. Several cholera prediction models have been developed based on these factors and may be critical in preventing epidemics.^{2,60,61,75,97,98} Recent evidence from Bangladesh and Haiti suggests that increases in vibrio-infecting bacteriophages can facilitate *V. cholerae* genetic evolution, affecting virulence and human infection, factors that may contribute to outbreak cessation and also allow epidemic-free periods in cholera endemic regions.^{108,109}

Host factors associated with susceptibility to *V. cholerae* include age, immunity, blood type, and reduced gastric acid production. Age groups commonly affected by cholera typically include young children because

susceptibility depends on preexisting immunity. In endemic areas such as Bangladesh, cholera cases are concentrated in the 2- to 9-year-old age category, followed by women of childbearing age.^{29,64} The increased susceptibility of children is further supported by a more recent prospective study in Kolkata, India, where cholera burden was greatest in children younger than 2 years, and cases were more likely where a household member had diarrhea.^{47,112} Mucosal humoral immune responses in both children and adults to *V. cholerae* may be decreased with intestinal helminth coinfection.⁴⁷ Breastfeeding protects against disease in children colonized with *V. cholerae*.^{29,41} Animal models suggest that offspring acquire passive immunity from vaccinated female mice.⁹³ Achlorhydric patients are at higher risk for acquiring infection because bacteria are more likely to survive the gastric environment and colonize the small intestine.⁸⁷ Observations of increased cholera severity among people with blood type O were confirmed through challenge and cohort studies,^{46,70} presumably because of blood type O antigen binding to cholera toxin.⁵⁰ For reasons that are not completely understood, individuals with the Lewis blood group Le(a+b-) phenotype may also be at increased risk for symptomatic disease in contrast to those with Le(a-b+) and Le(a-b-).⁷ Other host genetic factors likely also play a role, as evidenced by familial clustering of cases and gene association studies.^{43,65,69,95}

CLINICAL MANIFESTATIONS

Most individuals infected with *V. cholerae* have only mild symptoms, indistinguishable from symptoms caused by other enteric infections. Individuals who develop disease urgently need fluid resuscitation and replacement of ongoing losses. Among all causes of infectious diarrhea, the stool volumes passed and the rapidity by which dehydration develops are greatest with cholera.¹⁰⁶ In severe disease, stool volume can exceed 250/mL per kg body weight in a 24-hour period.^{81,94}

The most distinctive clinical feature of cholera is the painless passage of voluminous, watery stools. Termed “rice water stools” because of the watery, colorless diarrhea dotted with mucus, cholera stools may have a fishy smell or may be nearly odorless. Other common symptoms include abdominal cramping and vomiting. Abdominal cramping is probably due to increased abdominal secretions and resulting small bowel distention. Vomiting commonly occurs a few hours after diarrhea onset due to decreased gastric and intestinal motility, but it also occurs later in the course of the illness due to lactic acidosis.^{19,48,86,105} Patients with clinical symptoms do not typically present with fever.^{21,105}

Complications of cholera relate mostly to the massive intravascular volume and electrolyte loss. If cholera is not treated promptly, diarrhea and vomiting eventually lead to dehydration, which is most often isotonic. Patients with severe cholera may experience vascular collapse, shock, and death rates of 50%, starting within hours after diarrhea onset.¹⁰² Related to the massive intravascular volume loss and hypoperfusion, bicarbonate losses in stool, and hyperphosphatemia, acidosis also may develop.^{124,125} Compensatory tachypnea may be seen in patients with acidosis. In addition to bicarbonate losses in stool, potassium is also lost and may not be reflected in serum potassium levels; acidosis induces the intracellular potassium shift into the intravascular space in exchange for hydrogen ions, resulting in decreased total body potassium and potentially normal serum potassium values. As the acidosis is corrected, serum hypokalemia may result. In cases complicated by severe malnutrition, in which body potassium stores already are depleted, hypokalemia may be quite severe and manifest as paralytic ileus. This hypokalemia is rarely associated with severe cardiac arrhythmias, but it may manifest as changes on electrocardiogram.

After dehydration, hypoglycemia is the second most common cause of death in pediatric patients with cholera.¹² In one study, the mortality rate in pediatric patients with hypoglycemia caused by cholera was 15% in contrast to 1% mortality in patients with normoglycemia.¹² Although the precise mechanism of hypoglycemia is unknown, malnourished children who are acutely ill have lower glycogen stores and impaired gluconeogenesis. Special attention should be given to monitor patients with concomitant malnutrition and cholera for hypoglycemia.

Severe cholera is diagnosed in individuals who present with clinical signs and symptoms of severe dehydration (loss of $\geq 15\%$ of total body water or loss of $\sim 10\%$ of body weight). Common signs of severe volume

FIG. 117.1 An adolescent girl with severe dehydration from cholera. Characteristic features include obtundation, sunken eyes, and “tenting” of the abdominal skin and subcutaneous tissues after firmly pinching the abdomen.

depletion include a combination of decreased skin turgor, depressed anterior fontanelle in infants, lack of tears and sunken eyes, dry mouth, anuria, tachycardia, decreased peripheral perfusion, and hypotension (Fig. 117.1). In some cases, mental status changes may be a sign of volume depletion, but more common are somnolence, restlessness, and lethargy.

LABORATORY FINDINGS AND DIAGNOSIS

Laboratory abnormalities in patients with cholera relate to the massive volume and electrolyte loss. The hypovolemic state can lead to hemoconcentration, causing increased hematocrit, serum specific gravity, serum protein, serum creatinine, and blood urea nitrogen.^{124,125} Because of the sodium loss that accompanies water loss, serum sodium is either slightly low or normal.^{64,94} As noted earlier, although potassium loss occurs in the stool, serum potassium may be normal, whereas total body potassium may be decreased. Acidosis caused by bicarbonate loss in stool and lactic acidosis can result in a serum bicarbonate concentration of less than 15 mmol/L.^{124,125} Serum creatinine and blood urea nitrogen also are elevated as a result of a decreased glomerular filtration rate. The common abnormalities of sodium, potassium, bicarbonate, and glucose mandate early determination of serum glucose and electrolytes as a guide to therapy.

Although presumptive diagnosis is made on the basis of typical oxidase-positive colonies from stool samples that agglutinate with O1 or O139 antiserum, conventional culture methods remain the gold standard. The characteristically motile organisms can be visualized directly using darkfield microscopy,¹¹ but few laboratories except those in cholera-endemic regions are experienced with this technique. If cholera is suspected, special culture media, such as TCBS agar, should be used to culture the organism.

In epidemic settings or in areas of intense transmission, a rapid vibrio dipstick test may be used. This is a one-step immunochromatographic test developed by the Institut Pasteur for rapid detection of cholera O1 and O139 from stool samples. The method was tested in Madagascar, Bangladesh, and Mozambique, achieving 84% to 100% specificity and 94% to 100% sensitivity.^{88,123} It is especially advantageous because it requires minimal technical skill, can be read in 10 minutes,⁸⁸ and detects cholera from rectal swabs.^{15,123} Rapid diagnostic test specificity improves with alkaline peptone water enrichment of fecal samples.³⁸ Several other rapid diagnostic tools have been developed for field use including immunochromatographic lateral flow tests which can diagnose *V. cholerae* O1 serotype Ogawa within 5 minutes.²⁵ Confirmation of *V. cholerae* in stool also can be done using polymerase chain reaction amplification or oligoprobes.^{54,79,121}

TREATMENT

The cornerstone of cholera management is fluid resuscitation. When fluid resuscitation is initiated, previous losses must be estimated based

TABLE 117.1 Electrolyte Concentration in Cholera Stool and in Fluids Used for Rehydration and Replacement of Stool Losses

	ELECTROLYTE CONCENTRATION (MMOL/L)

WHO, World Health Organization.

^aOsmolality includes unmeasured osmotically active molecules (primarily organic acids) in addition to electrolytes.

^bAs citrate.

^cFrom electrolytes only; also contains 75 mmol/L of glucose.

^dAs lactate.

^eIntravenous solution containing 5 g sodium chloride, 4 g sodium bicarbonate, and 1 g potassium chloride per liter.

on the degree of dehydration and replaced, and ongoing losses must be quantified and replenished. Replacement fluids in children with cholera should be similar to fluids that are lost, such as lactated Ringer solution (Table 117.1).^{52,127} The ideal solution contains amounts of bicarbonate and potassium sufficient to replace what is lost in stool.

At the International Centre for Diarrhoeal Disease Research, Bangladesh, where thousands of cholera patients are treated annually, patients of all ages are seen with severe dehydration of rapid onset. Many arrive for treatment in hypovolemic shock. The extent of dehydration is determined, one or two intravenous catheters are inserted, and isotonic resuscitation solution is administered rapidly. The composition of the preferred solution at the Center (Dhaka solution) is listed in Table 117.1. The solution contains Na⁺, Cl⁻, K⁺, and HCO₃⁻, but no glucose. The complete estimated deficit is administered over the course of 4 hours, whereupon ongoing losses and maintenance fluids are provided. Serum glucose and electrolytes are determined rapidly, with glucose administration as needed based on these results. Because severely dehydrated patients characteristically are anuric, concern may exist over early potassium administration. The rapid onset of dehydration in cholera patients reduces this risk, however, and acute tubular necrosis is rarely seen.^{94,125} A greater concern may be the rapid shift of potassium from the circulation on correction of acidosis. Patients treated in this manner respond dramatically. After the 4-hour resuscitation phase, most patients can begin to accept oral rehydration solution. Close attention to fluids and electrolytes is required for the duration of diarrhea.

Although oral and intravenous rehydration methods are acceptable in theory for cholera management, the severity of losses in severe cholera renders intravenous rehydration the mainstay for treatment initiation in these cases. Not only do intravenous fluids allow predictable and rapid intravascular fluid volume expansion to occur, they also ensure timely replacement of ongoing losses that may be challenging because of excessive purging.⁹¹ As massive fluid volumes are lost in severe cholera, the volume deficit is frequently underestimated and rehydration therapy is often inadequate. Treatment of severe cases is best carried out by those with adequate training and experience in managing cholera. In cases where peripheral intravenous access is challenging, parenteral fluid resuscitation in severely dehydrated children can be achieved via scalp veins or via intraosseous access.¹⁰⁵ Mild cases can be managed with oral rehydration solution (see later discussion). Oral rehydration can also be administered via nasogastric tube in patients who are not

FIG. 117.2 A cholera cot is a simple folding cot covered with plastic that has a hole and bucket for collecting the stool output, as used for the care of cholera patients at the International Centre for Diarrhoeal Disease Research, Bangladesh. The bucket is calibrated, and the volume of stool (and replacement fluids required) can be calculated easily. The plastic sheet is cleaned daily and between patients.

able to drink or when IV access is problematic. Guidelines for the initial management of cholera in an outbreak setting have been published by the World Health Organization (WHO) Global Task Force on Cholera Control.¹²⁸

Use of a “cholera cot” is extremely helpful in quantifying ongoing fluid loss and for patient comfort (Fig. 117.2) and can easily be set up in cholera treatment centers. It is constructed of a simple cot with a hole in the center through which a plastic sheet drains into a graduated bucket below via a funnel. This allows for accurate quantification of ongoing losses and permits the patient to remain horizontal, an important advantage if the patient is initially hypotensive. Attention given to tachycardia and signs of hypoperfusion in prostrate patients is essential.

The WHO-approved oral rehydration salts (see Table 117.1) are recommended for patients with no detectable dehydration or mild dehydration, provided that the patient can drink sufficient quantities to replace the deficit and keep pace with ongoing losses. Oral rehydration solution can also be used for patients with severe dehydration to replace ongoing losses after initial intravenous replacement therapy. For cholera, oral rehydration solution that is made with rice rather than with glucose is preferred because carbohydrate reduces the purging rate.^{44,82,135} In resource-limited settings and remote areas, homemade oral rehydration salts can be prepared by dissolving half a small spoon of salt and six level small spoons of sugar in 1 L of clean water to initiate rehydration.¹⁰⁰ Food should be offered to patients as soon as they are able to eat, and breast-feeding in children should not be restricted. Supplementation with zinc reduces diarrhea duration and stool volume in children with cholera.¹⁰¹ Effective oral rehydration solution use requires extra effort in pediatric patients. Parents need instruction to encourage and supervise oral rehydration solution intake by the child, including taking as much as 20 ml/kg body weight per hour.²⁰ Parents also need reassurance that oral rehydration is still effective despite occasional vomiting.

A short course of antibiotics should be given to children with clinically significant cholera. This approach reduces the amount of diarrhea, the duration of illness, and the infectious dose in stools.^{42,102} Antibiotic therapy may also favorably affect transmission dynamics and hence have public health implications.⁸⁹ Because of high resistance rates in some areas, the organism should be isolated and tested for susceptibility using standard methods for gram-negative enteric bacteria. On average, patients not treated with antibiotics may continue to shed organisms for 5 or more days.⁷¹

Treatment options for cholera in pediatric patients are listed in Table 117.2. First-line therapies for *V. cholerae* in children include single-dose azithromycin or erythromycin for 3 days in younger children, and a single dose of doxycycline may be given to children older than 8 years. Tetracycline and doxycycline are generally not recommended

TABLE 117.2 Antimicrobial Therapy of Cholera^a

Agent	Single Dose	Multiple Dose
Azithromycin	20 mg/kg; maximal dose 1 g	
Erythromycin	Not evaluated	50 mg/kg/day erythromycin divided into 4 doses for 3 days; maximal dose 2 g/day
Doxycycline	2–4 mg/kg; maximal dose 300 mg	
Tetracycline	Not evaluated	50 mg/kg/day divided into 4 doses for 3 days; maximal dose 2 g/day
Ciprofloxacin ^b	20 mg/kg; maximal dose 1 g	30 mg/kg/day divided into 2 doses for 3 days; maximal dose 1 g/day
Trimethoprim-sulfamethoxazole	Not evaluated	10 mg trimethoprim/50 mg sulfamethoxazole/kg/day divided into 2 doses for 5 days; maximal doses 320 mg trimethoprim and 1.6 g sulfamethoxazole daily
Ampicillin	Not evaluated	50 mg/kg/day divided into 4 doses for 3 days; maximal dose 2 g/day
Furazolidone	7 mg/kg; maximal dose 300 mg ^c	5 mg/kg/day divided into 4 doses for 3 days; maximal dose 400 mg/day

^aAntimicrobial therapy is an adjunct to fluid therapy for cholera and is not an essential component. It reduces diarrhea volume and duration, however, by approximately 50%. The choice of antimicrobial agent is determined by the susceptibility pattern of local strains of *Vibrio cholerae* O1 or O139. Resistance to all agents has been reported and is common in some areas.

^bThe fluoroquinolones, such as ciprofloxacin, are only approved for use in children younger than 18 years in the United States for special indications because of concerns about arthropathy; multidose therapy has not been evaluated systematically in children, and recommendations are extrapolated from experience in adults.

^cSingle-dose therapy with these drugs has not been evaluated systematically in children, and recommendations are extrapolated from experience in adults.

in children younger than 8 years because of the risk for dental staining. In addition, ciprofloxacin is also effective against susceptible strains.⁸⁹ Trimethoprim-sulfamethoxazole has demonstrated efficacy in children,⁶² although resistance may be present among O139 strains.³ Both single-dose azithromycin 20 mg/kg and single dose ciprofloxacin 20 mg/kg achieved clinical success rates similar to a 12-dose course of erythromycin in children 15 years of age or younger, but ciprofloxacin was less effective in eradicating *V. cholerae* from the stool.^{67,104} Recently, single-dose azithromycin showed superiority to single-dose ciprofloxacin in children.⁶⁶

Multidrug-resistant *V. cholerae* strains have been isolated from both clinical and environmental settings, and the number of pathogenic strains resistant to one or more antibiotics is increasing.⁶⁸ Several different drug resistance mechanisms have been reported and include extended-spectrum β -lactamase production, enhanced multidrug efflux pump activity, plasmid-mediated quinolone and fluoroquinolone resistance, and chromosomal mutations.^{9,40,45,117} The horizontal transfer of resistance determinants with mobile genetic elements such as integrons and the integrating conjugative elements assist in drug resistance dissemination.⁴⁰ SXT, first identified in a *V. cholerae* O139 strain from India, is an integrating conjugative element carrying a resistance gene for trimethoprim-sulfamethoxazole, streptomycin, and chloramphenicol.⁴⁰ Appropriate antibiotics, usually prescribed before obtaining sensitivity testing results, should be administered according to local resistance patterns and should be monitored for changes in sensitivity. Antibiotic prophylaxis is not indicated for health care workers providing care to cholera patients.⁵⁶

PREVENTION

Because contaminated food and water are the main transmission routes of pathogenic *V. cholerae*, strategies to improve access to safe water sources and a clean food supply are the best methods for prevention. Proper sanitation methods also play a key role. During outbreaks, measures to increase awareness of cholera transmission and means to decrease spread should be communicated to the public. These measures include proper hand washing (especially after defecating), proper food preparation, and identifying ill individuals so they can be treated. Setting up an organized response amid explosive outbreaks is challenging in resource-limited settings, but a coordinated, multidisciplinary response can limit mortality and secondary transmission.¹¹⁸

Vaccination is another prevention method. Whole-cell, inactivated parenteral vaccines have been superseded by inactivated oral vaccines and are currently the only cholera vaccines commercially available and are used mostly as travel vaccines. The whole-cell plus B subunit vaccine (WC-rBS; Dukoral) consists of approximately 1×10^{13} inactivated whole cell classic and El Tor *V. cholerae* O1, serotypes Inaba and Ogawa with 1 mg of recombinant cholera toxin B subunit. The vaccine is WHO-prequalified and approved for children 24 months of age or older. It is

supplied as 3 mL single-dose vials that require refrigeration, each provided with a sachet of sodium bicarbonate buffer prepared by dissolving the contents in 150 mL of water immediately before consumption. Two doses administered at least 15 days apart are recommended for adults and three doses for children younger than 5 years of age. A large field trial in Matlab, Bangladesh, showed 85% protective efficacy for 6 months after vaccination among women and children older than 2 years,²⁷ but protection was not sustained in children younger than 5 years of age.²⁸ In Beira, Mozambique, one or more doses of WC-rBS vaccine during a mass campaign protected nearly 80% of children and adults against culture-confirmed cholera in a setting where the human immunodeficiency virus seroprevalence rate is 20% to 30%.⁷² All confirmed cases were due to an O1 El Tor Ogawa variant strain expressing the classic cholera toxin, indicating that the vaccine also provided protection against these newer cholera strains.³¹ The WC-rBS vaccine also may provide herd immunity in endemic settings.⁴

Two closely related oral vaccines are also available (mORCVAX and Shanchol). These killed bivalent (O1 and O139) vaccines do not contain the B subunit, do not require an oral buffer, and appear safe and immunogenic in trials conducted in Vietnam, India, and Haiti.^{5,22,58,74} including a study in HIV-seropositive Haitian women.⁵⁷ Protective efficacy after two doses was about 60% and remained near 50% for 3 to 5 years after vaccination.¹¹³ The Vietnamese vaccine (mORCVAX) is licensed and used nationally. The Indian vaccine (Shanchol) is prequalified by the WHO and licensed for use in adults and children older than 1 year of age. Two doses are administered in a 2-week interval, with a booster dose recommended 2 years after primary vaccination.³¹ Limited evidence suggests that oral cholera vaccination is safe in pregnancy.⁷³ During a cholera outbreak in Malawi's southern region in February 2015 affecting more than 160,000 people, the Malawi Ministry of Health initiated a mass vaccination campaign using Sanchol and targeting people aged 1 year and older, including pregnant women.^{132,133} An ongoing interventional study in the same region aims to assess inactivated oral cholera vaccination safety in pregnancy.³⁷

The live, attenuated cholera vaccine, CVD 103-HgR is genetically engineered from an O1 classic Inaba strain by *ctxA* subunit deletion and insertion of a marker mercury ion receptor gene into the chromosomal *hlyA* locus. Protection of 100% was seen against homologous strain in challenge studies of North American volunteers and lasts at least 6 months.¹¹⁴ It was previously licensed in the 1990s, but subsequently did not demonstrate protection in children or adults living in an endemic area,⁹⁹ potentially as a result of both direct and indirect protection.⁴ In an outbreak setting, however, a single dose provided 79% protection,¹⁸ making CVD 103-HgR more cost effective than the registered two-dose inactivated OCV regimens in terms of cases averted and fatalities.^{1,8,59,119} In 2015, the US Food and Drug Administration accepted a Biological License Application and granted priority review status for the CVD 103-HgR-based single dose OCV, Vaxchora, a step toward the first

licensed single-dose OCV for US travelers.⁵⁹ Phase 3 clinical trials of Vaxchora in Australia and North America enrolled more than 3000 participants total and showed a 90.3% and 79.5% efficacy rate against wild-type cholera challenge at 10 and 90 days postvaccination, respectively. Age-dependent immunity seen with CVD 103-HgR and other OCV products may be due to *Helicobacter pylori* gastritis and subsequent gastric acid secretion.⁸⁵ Several other candidate oral cholera vaccines, mostly live, attenuated, are under development, including Peru-15, a genetically engineered strain derived from an O1 El Tor Inaba strain,³¹ with safety and immunogenicity demonstrated in both healthy American²⁴ and Thai adults who are HIV seropositive.⁹⁶ Other live attenuated oral cholera vaccine under development include *V. cholerae* 638 and IEM 101/108 constructed from O1 El Tor Ogawa strain^{63,120} and VA1.3/VA1.4 derived from a nontoxicogenic O1 El Tor strain.⁶

Cholera vaccines should be used in conjunction with other prevention and control strategies in areas where the disease is endemic and considered in areas at risk for outbreaks.¹²⁹ The impact of reactive vaccination in response to outbreaks is less clear, although mathematical models predict a substantial benefit with prompt institution.³¹

Vibrio parahaemolyticus is recognized worldwide as a cause of foodborne disease associated with consumption of seafood—in particular, crustaceans and mollusks—and occasionally as a cause of wound infections and sepsis in immunocompromised hosts. *V. parahaemolyticus* was first isolated in 1950 and was associated with a foodborne outbreak in Japan traced to dried sardines. In this outbreak, there were 272 infections and 20 deaths.¹² The organism was originally classified as *Pasteurella parahaemolyticus* due to its similarity to other gram-negative rods with bipolar staining. Five years later, the halophilic bacterium was isolated from a patient with food poisoning and was renamed *Pseudomonas enteritis*. Almost 10 years after the original outbreak, the organism was classified correctly in the genus *Vibrio*,⁹ with the scientific name of *Vibrio parahaemolyticus*, and its distribution in coastal waters and estuaries of temperate climates around the world was recognized.⁸⁹ The regional differences in disease incidence are related to patterns of consumption of marine products and practices of food preparation. In Japan and Taiwan, where fish and shellfish are a major source of dietary protein and frequently consumed raw, *V. parahaemolyticus* accounts for 10% to 40% of foodborne outbreaks.^{80,103} In the United States, the incidence is lower, but with increasing consumption of raw or partially cooked seafood, *V. parahaemolyticus* is recognized as the leading cause of seafood-associated gastroenteritis. The first confirmed foodborne outbreak in the United States occurred in Maryland in 1971 and was linked to the consumption of contaminated crabmeat.²⁶ Since then, sporadic outbreaks have been reported,^{6,7,15,26,28,73,40,92} demonstrating the risk of infectious and toxic syndromes from marine products in the United States.³³ *Vibrio parahaemolyticus* can also cause wound infections, particularly in immunocompromised patients. An increase in such infections was reported in 2005 following Hurricane Katrina off the Gulf Coast of the United States; these infections were epidemiologically linked to exposure to brackish water in the hurricane areas.¹⁷

BACTERIOLOGY

V. parahaemolyticus is a gram-negative, non-spore-forming, curved rod with rounded ends that possess a polar flagellum.⁶⁵ On surfaces or in viscous environments, *V. parahaemolyticus* can differentiate into swarmer cells equipped with additional shorter lateral peritrichous flagella.⁶⁴ *V. parahaemolyticus* is a facultative anaerobe with respiratory and fermentative metabolisms. Similar to other *Vibrio* species, it is an oxidase-positive nonfermenter of lactose.⁸ It is arginine dihydrolase negative and ornithine decarboxylase positive. The requirement of sodium and enhancement of growth in a specific range of concentration differentiate it from *Vibrio cholerae* and *Vibrio mimicus*. Optimal growth occurs in solutions containing 2% to 4% sodium; concentrations greater than 8% sodium inhibits growth.¹⁰¹

V. parahaemolyticus produces round, blue-green colonies on the widely used *Vibrio*-selective thiosulfate citrate bile salt sucrose (TCBS) agar. This medium inhibits most fecal flora by the presence of bile salts and a highly alkaline pH. Direct plating on TCBS agar may be used for feces and other clinical specimens, but food samples that are not heavily contaminated require enrichment either in alkaline peptone water supplemented with 3% sodium chloride or in a strongly selective medium, such as Glucose Salt Teepol Broth.¹⁰¹ The optimal pH for growth is in the neutral range, but *V. parahaemolyticus* can survive in alkaline media. Optimal growth temperatures are between 35°C and 39°C (95°F–102.2°F).¹⁰⁹ Growth is rapid in conventional media and foodstuff, with generation times of only 8 minutes⁵⁰; a significant number of organisms can be found after only a short period of inappropriate storage. Growth is inhibited at temperatures of 44°C (111.2°F) or greater

and at temperatures less than 4°C (39.2°F). The degree of inactivation is greater with increased temperatures; a million-fold decline occurs in viable bacteria in shrimp homogenate kept for only 1 minute at 100°C (212°F).⁹⁹ In laboratory conditions with low temperature and nutrient supply, *V. parahaemolyticus* enters a viable but nonculturable state, during which the organism can no longer be cultured on routine growth media, but its viability can be confirmed using direct microscopic assays.^{35,49,107}

The genome of *V. parahaemolyticus* consists of two circular chromosomes. Genes for a type III secretion system (TTSS) were identified in a pathogenicity island on chromosome 2.⁵⁹ Two types of nonredundant TTSS have been identified.⁷⁷ TTSS, also a central virulence factor in both salmonellae and shigellae, possesses needle-like structures that facilitate direct injections of bacterial proteins into a target host cell and confers pathogenicity of the inflammatory diarrhea seen in *V. parahaemolyticus* infections. The presence of TTSS in *V. parahaemolyticus* differentiates its pathogenicity from that of *V. cholerae*, which does not carry these genes.⁵⁹

EPIDEMIOLOGY

In the United States, *V. parahaemolyticus* is found along the East, West, and Gulf Coasts, and an increasing number of outbreaks have been reported.^{19,29,50} Water, sediments, suspended particulates, plankton, fish, and shellfish have all been shown to harbor the organism.^{5,68} The organisms are present in highest numbers in water at temperatures between 17°C and 35°C (62.6°F–95°F) and containing 0.5% to 2.5% salinity.⁴⁸ Marked seasonal and geographic variations occur, with maximal mean concentrations occurring during late summer and spring along the Gulf Coast.²⁹ Outbreaks, predominantly between June and October, correlate with seasonal distribution of the organism.⁴

Finfish and all types of shellfish products—including oysters, clams, crabs, and shrimp—may be involved in the transmission of the infection.⁴⁸ The risk for acquiring infection is higher with molluscan shellfish due to their ability to concentrate the bacteria by filter feeding.^{5,35,109} In oysters, the density of *V. parahaemolyticus* may be 100 times greater than that in the surrounding water.²⁹ The levels of contamination are generally low in freshly collected oysters, with the highest mean density of only 160 bacteria/g found in the United States.²⁹ In Japan, high counts (up to 10³–10⁴/g) have been reported in market shellfish.²² The minimum infective dose is thought to be in the range of 10⁵ to 10⁷ organisms, based on volunteer feeding studies.³¹ More recent outbreaks of illness caused by oysters that met bacteriologic safety standards have raised questions about the adequacy of current food storage recommendations.²⁷ Noningestion *Vibrio* infection has been demonstrated in the marine-estuarine environment, potentially placing swimmers at risk for infection.⁸⁷

Between 1973 and 1987, shortly after the first outbreaks in the United States were reported, only 23 of 1869 foodborne disease outbreaks with known bacterial etiology reported to the Centers for Disease Control and Prevention (CDC) were caused by *V. parahaemolyticus*.⁶ In 18 of these outbreaks, a shellfish was recognized as the food vehicle. No fatal cases were reported. Contributing factors included inadequate cooking (92%), improper holding temperature (75%), and food acquired from an unsafe source (75%).^{6,7} Most affected individuals were adults, and no patterns of unusual susceptibility by age group or gender were noted. Unlike other bacterial and viral pathogens that cause gastroenteritis, secondary spread of *V. parahaemolyticus* does not occur between family members or other close contacts. Between 1988 and 1997, 345 sporadic cases were reported to the CDC. The majority of these infections (59%)

resulted in gastroenteritis and were related to ingesting raw oysters.²⁸ In the summer of 2006, outbreaks of *V. parahaemolyticus* associated with consumption of contaminated shellfish harvested from a common area were reported across the states of New York, Oregon, and Washington. Of these isolates, 78% tested had a subtype of O4:K12.¹⁸

Until more recently, *V. parahaemolyticus* infections were causally associated with multiple serotypes and occurred as sporadic cases or localized outbreaks.⁷⁰ In 1996, a sudden increase in infections was seen in India, and 50% to 80% of cases were attributed to a single serotype, O3:K6.⁷⁸ Shortly thereafter, O3:K6 strains were isolated from clinical samples from other countries in Asia.⁷¹ In 1998, two outbreaks of gastroenteritis in the United States were associated with O3:K6.^{16,28} By 2005, this pandemic clone was found in patients from Europe, South America, and Africa.^{3,39,63} Other clones that genetically diverged from O3:K6, such as O4:K68 and O1:KUT, were first isolated in the Pacific Northwest in 1988 and were responsible for large outbreaks in the United States in 1997 and 2004.^{25,66} Spread of these clones from the West Coast to the East Coast and to Europe traced to transport of seafood with improper storage.^{40,62,73} In 1997, oceanic eastward dispersion of *Vibrio* from Asia to the Americas was attributed to El Niño, which occurred the previous fall.^{60,62}

Although rates of *V. parahaemolyticus* stabilized during the late 2000s,³⁷ cases and outbreaks associated with these pandemic clones continue to be reported in high numbers globally.^{79,102}

Vibriosis became a notifiable disease nationally in 2007. Prior to routine reporting, the CDC relied on two surveillance systems to monitor the incidence of vibriosis in the United States. The Centers for Disease Control's *Vibrio* Surveillance (COVIS) system, initiated in 1988, is a passive surveillance system that relies on laboratories to report positive tests. The FoodNet system, established in 1996, is an active surveillance system for 10 states reporting *Vibrio* infections in addition to other foodborne enteric infections. Between 1996 and 2010, these surveillance systems demonstrated an increase in vibriosis overall, with the rise being driven primarily by an increase in *V. parahaemolyticus* infections reported by both systems (44.9% and 54%, respectively).⁷² FoodNet reporting from 2013 showed the highest incidence in *Vibrio* infections to date.¹⁰⁶ Although rates of *Vibrio* infections remain lower than those of *Salmonella* or *Campylobacter* infections, the overall incidence is increasing and may be related to rising surface seawater temperatures.^{61,105} From 1996 to 2010, there were 3460 and 820 *V. parahaemolyticus* infections reported by the COVIS and FoodNet systems, respectively. Of these 4280 cases, 845 (20%) patients were hospitalized and there were 28 (0.65%) deaths.⁷²

Given the specific culture media required for *Vibrio* isolation, and the limited access to more sophisticated diagnostic techniques, the number of infections reported to the CDC each year likely vastly underestimates the true number of infections. The CDC estimates that the number of *V. parahaemolyticus* infections approaches 4500 annually in the United States.²¹

PATHOGENESIS

The ability of certain strains of *V. parahaemolyticus* to produce β -hemolysis on Wagatsuma agar, known as the Kanagawa phenomenon (KP), was first epidemiologically associated with human pathogenicity.⁶⁷ KP is observed in the vast majority of strains from clinical specimens and in only rarely in strains from environmental sources.^{31,50,97} Thermostable direct hemolysin (TDH) produces KP.⁹⁶ TDH has a molecular weight of 42,000 consisting of two subunits of 21,000⁶⁸ and, in contrast to other hemolysins produced by *V. parahaemolyticus*, is not inactivated by heating for 10 minutes at 100°C (212°F). TDH is a pore-forming toxin that causes hemolysis by binding to and disrupting erythrocyte membranes.⁴⁴ TDH also has been shown to have enterotoxic activities, such as causing accumulation of fluid in rabbit ileal loop assays, invading intestinal mucosa,^{24,100} and increasing intracellular calcium concentrations that trigger secretion of chloride by intestinal cells.^{86,94,95} TDH is cytotoxic, lethal to small experimental animals, and cardiotoxic.¹¹¹

Certain KP-negative isolates from outbreaks have been shown to produce a TDH-related hemolysin (TRH).⁴⁶ Although TRH is heat labile, it shares similarities with TDH, such as hemolysis, production

of fluid accumulation in the rabbit ileal loop model, and induction of chloride secretion in human colonic epithelial cells.^{45,83} Likewise, some variants closely related to the original TDH by molecular analysis (Vp TDH/I and Vp TDH/II) have been isolated from KP-negative strains.⁶⁹ Both TDH and TRH are considered to be the major *V. parahaemolyticus* virulence factors, although the mechanism for enteric pathogenicity is not fully understood.

When the *tdh* and *trh* genes were cloned and sequenced, researchers realized that certain strains possess the genetic material but are phenotypically incomplete. Strains with a typical hemolysin-positive phenotype carried two chromosome gene copies, whereas *tdh* gene-positive strains with weakly positive or negative hemolysin phenotype possessed only a single chromosome gene copy.⁷⁵ Less than 50% percent of *trh* gene-positive strains produce TRH when examined by enzyme-linked immunosorbent assay.⁹¹ Low-level expression of the *tdh* genes may be the reason for the KP-negative phenotype.⁷⁶ The expression of the *tdh* genes is controlled by the Vp-toxRS operon. The basal production of mRNA and the degree of transcriptional activation seem to be related to differences in the nucleotide sequences and strength of the promoter region.⁷⁶ Studies have also suggested that conditions that simulate the human intestine, 37°C to 42 °C and the presence of bile, upregulate *tdh* gene expression, explaining increased production in pathogenic strains compared to those isolated from the environment.^{85,88}

Some studies, however, suggest additional virulence mechanisms and that the mere presence of the *tdh* or *trh* genes does not reliably correlate with virulence of a given strain.^{100,109} Up to 10% of clinical isolates have been shown to be TDH or TRH toxin negative by polymerase chain reaction (PCR).⁵⁸ *V. parahaemolyticus* requires intestinal colonization factors to cause disease. A variety of pili and other potential virulence factors have been isolated, but their roles are still incompletely defined.²² Adherence of *V. parahaemolyticus* to intestinal epithelial cells of rabbits²³ and human small intestine^{38,108} seems to require binding to complex carbohydrates or hemagglutinins of the host. A multivalent adhesion molecule, MAM7, conserved in many other gram-negative intestinal pathogens, appears to be a key factor in the initial attachment of bacteria to intestinal cells and is constitutively expressed, allowing for rapid attachment with host cells. *V. parahaemolyticus* can also disrupt epithelial barrier function, regardless of TDH and TRH production.⁵⁸ Type 3 secretion systems 1 and 2 are organelles that span the bacterial inner and outer membranes and likely facilitate bacterial toxin delivery into the eukaryotic cell, resulting in cytotoxicity. Like the TDH and TRH system, the expression of these virulence factors is influenced by the presence of bile acids and higher temperatures.^{12,112}

Additional virulence factors include a capsule and two different types of flagella with distinct functions for swimming and swarming. These factors likely aid the organism in the colonization and infection of the human host and enhance its survival in the environment.⁵⁶

The occurrence of cases with grossly bloody stools^{15,47} is suggestive of the organism's invasiveness and is consistent with the production of cytotoxin.¹ KP-positive and KP-negative strains from clinical specimens can invade and colonize the mucosal cells of the rabbit ileum, producing acute inflammation, degeneration, and erosion of the villi.⁸ *Vibrio* infection is not isolated to the intestinal lumen; organisms can be cultured from tissue specimens of spleen, liver, and heart in experimental animals, indicating spread through the lymphatic or circulatory systems.¹¹

CLINICAL MANIFESTATIONS

The spectrum of intestinal disease varies from mild gastroenteritis to dysenteric syndrome. The incubation period is typically 15 to 24 hours (range, 4–96 hours)^{4,93}; this variability is likely related to the number of organisms ingested. Resolution of symptoms usually occurs after approximately 3 days⁶⁸ but varies from several hours to more than 10 days.^{4,13} Diarrhea (96%) and abdominal pain (95%) are the most common and earliest symptoms, accompanied by nausea, vomiting, and headache in 40% to 70% of cases. Chills and moderate fever are less frequent (20%).^{4,26} Diarrhea caused by *V. parahaemolyticus* is watery and explosive,¹⁴ with patients having up to 15 stools during the first day. Shock caused by loss of intestinal fluid is unusual but has been reported.²⁹ Diarrheal stools may contain mucus, but grossly bloody stools are less common.^{9,47,57} Small

superficial ulcerations may be seen on sigmoidoscopy.⁹ No difference in symptoms exists in cases caused by KP-negative strains.⁴⁴

V. parahaemolyticus can also cause wound infections and septicemia. COVIS, initiated in 1988 in four Gulf Coast states, demonstrated that 18% to 34% of *V. parahaemolyticus* isolates were isolated from wound infections, and 3% to 5% were associated with septicemia.^{27,57} In 2009, 11% of isolates from the United States were obtained from wounds and 2% of isolates from blood cultures.²⁰ Wound infection occurs after contamination of skin lacerations with seawater or after direct trauma with pieces of shellfish, fish hooks, or utensils contaminated with seawater.¹⁰ Superficial infection can extend to deeper soft tissue and, in some cases, lead to fatal necrotizing fasciitis.⁸¹ Septicemia is of most concern in immunocompromised patients, particularly patients with leukemia³¹ and liver disease.^{30,41} Bacteremia may develop after either wound infection^{10,31} or ingestion of seafood.^{41,84} Skin bullae,⁴¹ intravascular hemolysis,³¹ and disseminated intravascular coagulation⁴¹ may also complicate wound and bacteremic infections.

COMPLICATIONS

An acute diarrhea episode may require medical attention but less frequently leads to hospitalization.^{13,26,57,93} Children younger than 5 years of age are more likely to require hospitalization compared to older individuals.⁹⁸ Long-term sequelae from *V. parahaemolyticus* infection is unusual, although severe dehydration, shock,^{47,82} and death (0.04% of cases in Japan) can occur.^{8,101} Primary septicemia,^{54,57,84} septicemia secondary to wound infection,^{10,31,54} and septicemia secondary to gastroenteritis^{41,54} have higher mortality rates, especially in immunosuppressed patients or in patients with liver disease.^{10,34}

DIAGNOSIS

Epidemiologic data are the basis for the presumptive diagnosis. In a patient with compatible symptoms, a history of recent seafood consumption or exposure to warm seawater should suggest the diagnosis. Leukocytosis and fecal leukocytes may be found^{9,47} but are nonspecific findings. A positive stool culture on selective media, such as TCBS agar, can confirm the clinical impression. Routine use of TCBS agar, however, is not cost-effective, even in coastal areas, unless an appropriate clinical setting is available.^{10,57,65} The use of a transport medium, such as Cary-Blair (Thermo Fisher Scientific), is necessary if a delay in sample processing is expected. Isolation of more than 10⁵ *V. parahaemolyticus* from epidemiologically implicated food supports the diagnosis and identifies the vehicle.⁶⁵ A correlation between the serotype found in the food and the clinical isolate is not always present because multiple strains can contaminate a single food.⁴ Adding an enrichment broth to the processing increases the yield of isolation. The use of chromogenic (chromogenicCHROMagar *Vibrio* [CV] agar) agar has facilitated the identification and isolation of *V. parahaemolyticus* and has simplified laboratory differentiation of *V. parahaemolyticus* from other *Vibrio* species. Generally, culture methods are laborious, have low sensitivity, and are not able to distinguish pathogenic strains from nonpathogenic strains. More advanced diagnostic techniques, such as immunoassays and PCR, are preferable and becoming increasingly available commercially.⁴³

For testing blood specimens, use of routine culture media followed by selective media is appropriate.^{41,84} Immunoassays (enzyme-linked immunosorbent assay, immunoprecipitation in agar medium, reversed passive latex agglutination) are available in research laboratories and commercially in Japan (KAP-RPLA, Denka Seiken; BT test, Nissui Pharmaceutical) to detect the TDH. Strains producing TRH may be detected by cross reactions.¹¹⁰ DNA probe hybridization⁷⁴ and PCR with a sequence of a highly conserved DNA fragment⁵⁵ or targeting the *tdh* or *trh* genes can be used to detect low numbers of the organism in environmental and clinical specimens.^{52,53} Loop-mediated isothermal amplification is a newer technique⁵⁶ that does not require thermal cycling and has been used to identify *tdh* and *trh* genes in addition to other genes encoding virulence factors in *V. parahaemolyticus*. Serologic methods (slide agglutination) can detect H antigens in lateral flagella.⁹⁰ Histologic findings from duodenal and rectal biopsy samples from patients infected with *V. parahaemolyticus* show a nonspecific acute

inflammatory response, with epithelial degradation, polymorphonuclear neutrophil infiltration of villi and crypt cells, and hemorrhage.⁸³

TREATMENT

For the management of gastroenteritis, supportive therapy with careful attention to fluid and electrolyte balance is indicated. Oral rehydration is usually appropriate, although intravenous fluids may be required if massive fluid losses and significant dehydration occurs.^{9,47,82} Antibiotic treatment for most *V. parahaemolyticus* infections is unnecessary, as it is a self-limited disease. For protracted cases, tetracycline or a fluoroquinolone may be beneficial.^{8,9,50}

For wound infections and septicemia, antibiotics are always indicated. Patients with septicemia should be treated with a third-generation cephalosporin plus doxycycline. Trimethoprim-sulfamethoxazole plus aminoglycoside is an alternative regimen for young children. Penicillins are ineffective because of the presence of β -lactamases in 50% of isolates.^{36,51} Multidrug-resistant strains have been reported in fresh and frozen oysters as well as in water samples.² Few clinical strains have been shown to be resistant to trimethoprim-sulfamethoxazole, third-generation cephalosporins, aztreonam, imipenem, fluoroquinolones, and aminoglycosides.^{10,31,36,41} Wound infections with necrotic tissue require surgical debridement.

PREVENTION AND CONTROL

Ensuring the lack of contamination of seafood is difficult, but avoiding food-handling errors decreases the risk for infection. A recommendation for an acceptable upper limit of 100 colony-forming units per gram of *V. parahaemolyticus* in raw shrimp was established by the International Commission on Microbiological Specification for Foods.⁴⁸ Heating seafood to 60°C (156.2°F) for 15 minutes³² or boiling for 7 minutes¹³ seems to be adequate to reduce the risk for infection; thorough cooking eliminates the organism.⁹⁹ When undercooked or raw seafood is consumed, adequate refrigeration prior to ingestion to preclude multiplication of organisms is important. Cooked seafood that comes in contact with contaminated water can also transmit infection; thus, attention to food service is critical to preventing infections. During the preparation of seafood, special attention should be paid to possible cross-contamination. Use of the same utensils, board surfaces, or containers for fresh and recently cooked seafood should be avoided.^{82,99} Finally, raw seafood consumption should be discouraged, particularly for individuals at high risk for development of septicemia.^{30,54,57} Governmental regulations established in 1999 in Japan guiding the collection, storage, and preparation of seafood resulted in significant declines in *V. parahaemolyticus* infections, specifically those due to pathogenic TDH producing serotype 03:K6.⁴² Investigation into new and novel methods to prevent seafood contamination with pathogenic *Vibrio* while preserving the taste of the food will be important to reduce future outbreaks and maintain the safety of seafood consumption.¹⁰⁴

Vibrio vulnificus

Randall G. Fisher

BACTERIOLOGY

Vibrio vulnificus is a small, curvilinear, gram-negative rod of the family Vibrionaceae.⁷ This facultative anaerobe is oxidase positive and lysine positive, similar to other species of the genus *Vibrio*. Its major difference is that it ferments lactose, a feature that accounts for its original name, Lac + *Vibrio*. *V. vulnificus* is arginine negative and ornithine variable. This halophilic (salt-loving) organism grows in concentrations of sodium chloride of 1% to 8% and seems to grow best at approximately 3%.³⁹

EPIDEMIOLOGY

V. vulnificus, similar to *Vibrio parahaemolyticus*, is a marine organism that is a common inhabitant of offshore waters, especially estuarial waters.⁶² It has been isolated from sediment, plankton, water, finfish, crabs, and oysters.⁷⁰ Peak recovery occurs in the summer and early fall,¹⁸ possibly because at higher water temperatures *V. vulnificus* is released and rises to surface waters. There, it attaches to plankton and shore fish and then is taken up and concentrated by filter-feeding mollusks and crustaceans.

V. vulnificus has been isolated from wild and commercial oysters throughout the world. It especially is prevalent in warm coastal waters. Reports about the survival of the organism in oysters stored at low temperatures are conflicting.³³ Nilsson and associates⁶⁰ revealed, however, that even if *V. vulnificus* is rendered nonculturable by storage at low temperatures, it can be “resuscitated” by allowing the oysters to warm up to room temperature. This cycle could be carried out twice without any reduction in bacterial count. Because of the ubiquity of the organism in the marine environment and its ability to thrive under even the most careful conditions of sanitation, storage, and transport,^{17,37} ensuring that commercial shellfish do not contain viable *V. vulnificus* is very difficult.

So-called heat shock shucking, during which the internal meat temperature exceeds 50°C (122°F) for 1 to 4 minutes, reduces the *V. vulnificus* and total bacterial levels in oysters 10-fold to 10,000-fold

compared with conventional processing.²³ A separate study confirms that low-temperature pasteurization, which brings oyster temperatures to 50°C for 10 to 15 minutes, reduces colony counts from greater than 100,000/g of oyster meat to undetectable levels.² Ice immersion for 3 hours is ineffective at reducing *V. vulnificus* and actually increases coliform counts in oysters.^{61,65} High-pressure processing is a promising new approach to eliminating *V. vulnificus* from oysters; in preliminary studies, *V. vulnificus* could be reduced to undetectable levels by processing at 586 MPa with a 7-minute “come up” time.⁴⁰

Disease in humans is initiated by contact with the organism. Contact occurs either through marine contamination of a wound or in the gastrointestinal tract after ingestion of the organism in raw shellfish, most commonly oysters.⁷ The incidence of disease caused by *Vibrio* species, including *Vibrio vulnificus*, almost tripled (from approximately 0.09 to 0.3 per 100,000 population) in the United States from 1996 through 2010. *V. vulnificus*, not surprisingly, caused the most hospitalizations and death.⁵⁹

PATHOPHYSIOLOGY

V. vulnificus causes three distinct diseases in humans: wound infection and gastrointestinal infection, which may be self-limited or progress to septicemia. Local infection occurs after a wound is exposed to contaminated seawater. Wound infections with *V. vulnificus* are marked by rapid spread, the formation of bullae, and necrosis of involved tissues.⁷ Marked edema and vascular thromboses occur in experimental and natural infection. *V. vulnificus* elaborates a cytolyisin,^{21,22,39,43} a collagenase,⁶⁸ and a protease,⁵⁴ which enhance its rapid spread in tissues. The protease activates the plasma kallikrein-kinin system to produce bradykinin⁵³; histamine also is released locally. These factors account for the intense inflammatory reaction seen in these lesions. One group of researchers constructed an isolate that lacked a flagellum and found that its ability to adhere to cells was decreased, as was its lethality in mice.⁴⁸ Another group found that three different TonB systems (these transport iron-bound substrates across the bacterial outer membrane) are required for flagellar biosynthesis.²⁰ Hemorrhagic complications may be due to

the presence of a metalloprotease that interferes with blood homeostasis through prothrombin activation and fibrinolysis.¹¹

In otherwise healthy individuals, a mild, self-limited gastrointestinal illness similar to that caused by *V. parahaemolyticus* has been described.³⁸ The most serious infection produced by *V. vulnificus* is primary septicemia, which occurs most commonly in patients with liver disease after they have ingested the organism in raw shellfish.^{8,52,53} The organism contains an elastase called VvpE that mediates disruption of intestinal tight junctions, allowing access to the bloodstream.⁴⁶

For patients with hepatic disease, the risk for acquiring septicemia is 40 to 80 times greater, and the case-fatality rate is 2.5 times higher than for otherwise healthy individuals.²⁵ *V. vulnificus*, similar to many other gram-negative organisms, requires iron for growth and grows better in an excess of iron.⁷⁸ It is able to extract iron from hemoglobin, even if it is complexed completely to haptoglobin.^{78,82} Liver damage, excess iron, deferoxamine therapy, and hepcidin deficiency³ have been shown to decrease the median lethal dose (LD₅₀) of *V. vulnificus* in experimental animals. Deferoxamine alone decreased the LD₅₀ by four orders of magnitude.⁹ Iron overload almost certainly underlies *V. vulnificus* septicemia in patients who require repeated transfusions and deferoxamine therapy for anemia.^{32,80} Some evidence indicates that alcoholism, even in the absence of demonstrable liver disease, is a risk factor for developing sepsis.⁶³ Fatal septicemia has been reported in patients with other chronic diseases, such as diabetes mellitus and lymphomas.⁶⁴

Virulence factors of the organism have been described.⁷⁹ Virulent strains are resistant to the bactericidal activity of human serum,⁴² probably because of the presence of a polysaccharide capsule.¹ Poor uptake of virulent strains into phagocytes⁷¹ and opaqueness of the colony on agar have been correlated with the presence of the capsule.^{67,79} RTX toxin is a cytotoxin that also may be important in protecting the organism from phagocytosis.⁴⁹ No difference has been shown in the lipopolysaccharides of virulent versus avirulent strains.⁶ The production of recalcitrant shock in patients with septicemia is secondary to toxins, loss of vascular tone, capillary leak, and possibly negative inotropy, as in other forms of gram-negative sepsis.

CLINICAL MANIFESTATIONS

Patients commonly have wound infection or primary septicemia. Wound infection occurs after injury in seawater or after the contamination of a recently acquired wound with seawater. Often, the wound is caused by the shell of a crustacean or mollusk. Many patients with wound infections work in shellfish-related industries. Apparently, wound infection with *V. vulnificus* can develop from superficial wounds acquired within 24 hours of “uneventful” fish handling; the physiologic characteristics of human sweat may be conducive to the survival of the organism on the skin, allowing for later inoculation.¹⁰ A worker at a fish hatchery who had other risk factors, including diabetes mellitus and fatty liver disease, developed necrotizing fasciitis from acupuncture therapy, again suggesting prolonged survival on the skin.⁴¹ Cellulitis may develop and spread rapidly. Overlying skin often is covered with tense bullae. At debridement, the extent of necrosis may exceed presurgical expectations.⁷⁷ Primary wound infection may progress to systemic infection; for this reason, wound infection with *V. vulnificus* carries a mortality rate of 7% to 24%.^{7,38} Findings associated with mortality in patients with necrotizing fasciitis include low white blood cell counts, low platelet counts, hypoalbuminemia, high immature neutrophil percentages, and hypotension at presentation.⁷⁴

Patients with primary septicemia generally give a history of recent (i.e., 6 to 72 hours) consumption of raw seafood. Illness is marked by the rapid onset of fever, hypotension, and septic shock. Prodromal symptoms—such as malaise, chills, and fever—are common manifestations. Vomiting and diarrhea are seen in approximately 20% of patients.⁸ Shock progresses quickly and is difficult to reverse. Secondary skin lesions develop in approximately half of patients⁷ and may be bullous, petechial, or maculopapular. *V. vulnificus* frequently is isolated from cultures of secondary lesions, providing evidence of septicemic spread to those sites.⁷ The mortality rate from primary septicemia has been reported to be 46% to 79%.^{8,63} A poor outcome is portended by pH

less than 7.35,⁸¹ white blood cell count less than 10,000/μL, platelet count less than 100,000/μL, creatinine greater than 1.3 mg/dL, albumin less than 2.5 g/dL, increased prothrombin time, multiple skin lesions (implying septicemic spread), and delay in initial therapy.⁴⁵

In addition to causing the described syndromes, *V. vulnificus* has been reported as a cause of corneal ulcer,¹⁹ myositis,³⁴ adult epiglottitis,⁵⁰ osteomyelitis,⁷⁵ endocarditis,⁷³ peritonitis,²⁷ tubo-ovarian abscess,⁵¹ and meningitis.^{32,63} In one case, a patient had endogenous endophthalmitis without systemic symptoms that developed after ingestion of raw seafood.³¹ A case of fatal septicemia has been described in which the presenting symptom was a compartment syndrome of the forearm.²⁹ A 9-year-old girl with thalassemia and iron overload had septic arthritis as the presenting feature of her septicemia.⁴⁴ Ninety percent of reported patients are 40 years old or older.^{7,63} Childhood cases of septicemia have been associated with thalassemia major,³¹ for which frequent transfusions and deferoxamine therapy are required. Wound infections in previously healthy children and adolescents have been reported. *V. vulnificus* also has been isolated from a premature infant's stool sample obtained on the infant's first day of life; the infant's mother worked as an oyster shucker.⁵

DIAGNOSIS

The diagnosis of *V. vulnificus* infection is made by isolating the organism from blood or tissue culture. It also may be recovered from stool specimens.^{5,64} Agars designed specifically to aid in the growth and identification of *V. vulnificus* have been developed; cellobiose-colistin agar outperforms thiosulfate citrate bile salts sucrose agar for recovery of *V. vulnificus* from environmental samples.²⁶ From a practical standpoint, however, most hospital microbiology laboratories do not stock cellobiose-colistin agar. Of the commercially available media, *V. vulnificus* tends to grow best in thiosulfate citrate bile salts sucrose agar,⁷ but it also may be recovered from ordinary blood agar plates^{4,66} or MacConkey plates.⁷

A very sensitive nested polymerase chain reaction technique that is capable of detecting 1 pg of bacterial DNA and one colony-forming unit of *V. vulnificus* has been described; it was positive in 94% of clinical samples that grew the bacteria in culture and in 42% of culture-negative samples from patients with suspected *V. vulnificus* infection.^{24,47} A multiplex polymerase chain reaction was developed that had 100% sensitivity and specificity for identification and differentiation of *V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus* in validation tests with 488 strains.⁵⁷ An enzyme immunoassay also has been developed.⁷¹

The diagnosis of *V. vulnificus* wound infection or septicemia can be suspected on clinical grounds and appropriate therapy initiated while awaiting culture results. A history of ingestion of raw shellfish or contamination of a wound with either seawater or brackish inland waters⁵⁹ should be sought. *V. vulnificus* infection should be given high consideration in patients with hemosiderosis, anemia with transfusion therapy, liver disease, or other chronic diseases.

TREATMENT

For severe wound infections and necrotizing fasciitis, performing surgical therapy as rapidly as possible is paramount. In some cases, in which septic shock combined with multiorgan system dysfunction syndrome makes prolonged surgical procedures difficult or impossible, temporizing with rapid incision and drainage followed by full debridement 24 hours later may be a feasible approach.²⁸ However, in a large retrospective study, debridement within 12 hours of admission held the most favorable prognosis.¹² For primary septicemia, support of the patient's airway, along with aggressive pressor support and other adjunctive therapies for severe septic shock, is of primary concern. Secondarily, appropriate antibiotic treatment for *V. vulnificus* should be started as early as possible.⁵⁵

In vitro, the organism is susceptible to many antibiotics, including ampicillin, third-generation cephalosporins, fluoroquinolones, tetracycline, chloramphenicol, and gentamicin.⁷ Most of what we know about effective antimicrobial therapy for *V. vulnificus* sepsis comes from mouse studies and retrospective human case series. In the mouse model, ciprofloxacin is the single most effective agent, and the combination

of ciprofloxacin plus cefotaxime tends to have the highest survival rate³⁰ despite the fact that cefotaxime by itself has virtually no salutary effect. In humans, similarly, mortality rates are highest when cephalosporins are used by themselves¹⁶ despite good minimum inhibitory concentrations in the laboratory. Combination therapy with cefotaxime and minocycline or cefotaxime and ciprofloxacin looks far superior, with the latter combination being perhaps the best.

In the largest retrospective case series, outcomes were similar in those who received a fluoroquinolone with or without minocycline and those who received a third-generation cephalosporin plus minocycline. Mortality was 61% in those who were treated with a third-generation cephalosporin alone.¹⁴ In vitro synergy studies show that the combination of ciprofloxacin and cefotaxime is synergistic for *V. vulnificus*,³⁶ and in a murine model, the newer fluoroquinolones (e.g., moxifloxacin) worked as well as combination therapy in preventing lethality in mice.¹⁵ Given these data, combination therapy with ciprofloxacin and cefotaxime should be used without regard to the age of the patient.

In vitro, the addition of the iron chelator deferasirox to antimicrobial treatment (in this study, ciprofloxacin) resulted in synergistic antimicrobial activity.⁵⁸ One case has been reported of a patient iron-overloaded from hemochromatosis who survived after treatment with the combination of ciprofloxacin and deferasirox.³⁵

The addition of modified Dakin solution (0.025% sodium hypochlorite) may have some utility in the treatment of skin and wound infections. An in vitro study of eight topical antibiotic preparations showed that *V. vulnificus* was most sensitive to modified Dakin solution.⁵² Although no controlled trial has been performed, a series has been reported of 10 patients with culture-proved *V. vulnificus* wound infections treated with doxycycline and topical modified Dakin solution, none of whom experienced progression of infection or required surgical debridement.⁷⁶ Autologous platelet concentrate spray was used successfully as adjunctive wound therapy in a renal transplant patient.⁷²

PREVENTION

Patients with severe anemia, liver disease, hemosiderosis, or other debilitating chronic diseases and patients on deferoxamine therapy should be advised against eating raw seafood of any kind. Awareness

of the disease has been shown to be low in high-risk patients; physicians need to educate at-risk patients.⁵⁶ Patients with open wounds probably should avoid contact with seawater or brackish inland waters. In a mouse model, intramuscular VvpE (a recombinant metalloprotease/elastase antigen of *V. vulnificus*) elicits a good antibody response and confers protection against lethal challenge.¹³

Miscellaneous Non-Enterobacteriaceae
Fermentative Bacilli

Randall G. Fisher

Fermentative bacilli that are not of the family Enterobacteriaceae are discussed in this chapter. Specifically examined are *Chromobacterium violaceum*, *Plesiomonas shigelloides*, and *Pasteurella* organisms other than *Pasteurella multocida*.

CHROMOBACTERIUM VIOLACEUM

C. violaceum is a facultatively anaerobic, gram-negative rod that is a saprophyte of soil and water and is found especially in tropical and subtropical climates. It causes occasional illness in animals and, rarely, in humans. Infection with *C. violaceum*, when it does occur, is a serious disease with a high mortality rate.

Bacteriology

C. violaceum is a long, motile, gram-negative bacillus that appears singly or in pairs on Gram stain. It has a polar flagellum and one to four subpolar or lateral flagella that antigenically are distinct from the polar flagellum.⁹⁶ Most isolates produce an insoluble pigment, violacein. This

pigment is intense and makes colonies appear dark purple to black, especially on blood agar. Violacein induces apoptotic death in certain cell types in vitro, including leukemia and lymphoma cells.⁷² The therapeutic potential of violacein and structural analogs is being explored. Violacein also has antibacterial, antitrypanosomic, antimalarial,⁶⁵ and weak antiviral effects.⁸ In a rat model, violacein displays immunomodulatory, analgesic, and antipyretic effects¹¹; in addition, it protects against gastric ulcers¹² and is an effective treatment for diarrhea.¹³ *C. violaceum* grows readily on standard agar (any medium that contains tryptophan supports growth). The colonies are low convex, violet, smooth, and not gelatinous. Colonies produce hydrogen cyanide; thus, a faint almond odor may be present.⁹⁶

C. violaceum is catalase positive and oxidase positive, although the latter may be difficult to interpret because of the production of pigment. Growing the organism anaerobically inhibits pigment formation.⁵⁸ Pigment also may be lost on subculture⁸⁵ or as effective treatment is initiated. *C. violaceum* has a fermentative, not oxidative, attack on carbohydrates.

Epidemiology

C. violaceum commonly is found in soil and water of areas with tropical or subtropical weather patterns. It also has been recovered from soil as far north as New Jersey.²⁸ Ten of the first 12 cases reported in the United States occurred in Florida; the other two were in Louisiana. Subsequently, one case from New Jersey⁷⁹ and one from Ohio⁹⁸ have been reported, along with more from southeastern states. All but one case occurred during summer.⁸⁵ Patients tend to be young, with a median age of 14 years.⁸⁵

Pathophysiology

Although *C. violaceum* is a common inhabitant of soil and water, human infection is rare. Disorders of neutrophil function are important risk factors. A disproportionately high number of *C. violaceum* infections have occurred in patients with chronic granulomatous disease⁶⁷ (CGD); in one case, *C. violaceum* septic shock with multiple skin, liver, and lung abscesses was the presenting feature of CGD.⁸⁸ *C. violaceum* infection in a child with another disorder of neutrophil function, polymorphonuclear leukocyte glucose-6-phosphate dehydrogenase deficiency, has been reported.⁶⁸ Organisms may show variable virulence, and differences in endotoxin activity, resistance to phagocytosis, and production of catalase and hydrogen peroxide have been observed between clinical and soil isolates.⁷⁶ An elastase activity, expressed through the entire life cycle and produced by a zinc metalloproteinase, may account for the propensity of *C. violaceum* to cause abscesses.¹¹³ Because *C. violaceum* is a free-living organism that is exposed to diverse environmental conditions, it exploits a wide range of energy resources and is able to thrive in aerobic and anaerobic conditions.²⁷ It is equipped to be tolerant of harsh conditions, including acid and ultraviolet stress, temperature stress, heavy metal exposure, and antibiotic exposure.⁵⁰ The complete sequencing of its genome has allowed researchers to identify putative virulence genes that are likely involved in host cell adhesion, cell invasion, and cytolysis.¹⁹ Cytotoxicity is caused by pore formation on host cell membranes; this is mediated by a type 3 secretion system product of pathogenicity island 1.⁷⁵ A *Serratia*-type hemolysin has also been described.²¹ *C. violaceum* is able to produce an exopolysaccharide biofilm.¹⁶

The organism usually gains entrance to the body through cuts or abrasions that come in contact with contaminated soil or water. After entrance, a localized infection usually develops at or around the site of entry, which is commonly followed by dissemination of infection via the bloodstream to distant sites. Rapid debridement and appropriate antibiotic therapy may arrest the infection at the wound stage.⁶² Two cases of systemic infection occurred in near-drowning victims. One case report describes fulminant infection and death in an immunocompetent host from *C. violaceum* sepsis that began as conjunctivitis after a fall that splattered mud into the patient's eye.³³ Another severe case with sepsis and multiorgan dysfunction began as a small prick injury to a finger.¹⁰ Numerous microabscesses are found in multiple organs, especially liver, lung, and kidneys. Spread to bone, joints, and the central nervous system also has been described.

Clinical Manifestations

The pattern of illness in all reported patients is similar, with a contaminated inoculation site, localized disease, regional lymphadenopathy, and hematogenous spread to visceral organs. Progression of symptoms tends to be rapid after a variable incubation period.

Most patients have cutaneous lesions,⁶⁷ which are described as being nodular or pustular and sometimes with surrounding cellulitis.¹⁰⁴ They may progress to suppuration and drainage or to ulceration. Occasionally, classic ecthyma gangrenosum lesions have been described.²⁰ Regional lymphadenopathy is common; some of the nodes suppurate and require surgical drainage or removal.

Severe disease is heralded by high fever (39°C–41°C [102.2°F–105.8°F]), confusion or lethargy, abdominal pain, headaches, nausea and vomiting, and sometimes myalgias. Patients with systemic illness appear toxic. Hepatosplenomegaly develops frequently, and jaundice may be present. Progression from high fever and moderate toxicity to septic shock with disseminated intravascular coagulation and multisystem

organ failure is precipitous.¹⁰ After the liver, the lung is the most common site of dissemination of infection, and evidence of pneumonia often is found. Adult respiratory distress syndrome is rare.⁶³ Brain and liver abscesses have been noted.⁷⁷ The overall mortality rate is 65%.⁶⁷ Rarely, there may be recurrence, which can prove fatal.^{58,85} A review of all 25 pediatric cases reported between 1971 and 2005 revealed, counterintuitively, that the case-fatality rate was 12 of 16 (75%) in patients without CGD and in none of 9 in patients with a known diagnosis of CGD.⁹⁴ One case in a patient with CGD who suffered three separate episodes of *C. violaceum* sepsis has been reported.¹⁰⁰

A review of all cases reported between 1952 and 2009 (N = 106) found that all patients had fever. Sepsis developed in 82% of patients. Localized abscesses were found in about half of the patients, with the liver being the most common site. Relapse occurred in 6.6%, with a median interval of 135 days. Risk factors for mortality were young age at diagnosis, the presence of a localized abscess, a shorter clinical course, and inappropriate initial antimicrobial therapy.¹¹⁰

Diagnosis

Diagnosis is made by recovery of the organism from blood, lymph nodes, skin lesions, or abscesses. Gram-negative bacilli sometimes can be seen in smears or grown in culture¹⁰ of material from skin lesions. Laboratory values reveal either very low or very high white blood cell counts with marked left shifts. Mild to moderate anemia is common. Serum levels of liver enzymes may be elevated, and evidence of early renal failure sometimes is present. The organism grows readily and is easy to identify if it produces the characteristic violet pigment. Non-pigmented forms exist in soil and have similar virulence in mice⁹⁵ but are recovered only rarely from clinical specimens.⁹⁸ Other cases may have been missed, however, because the nonpigmented forms often are misidentified as *Aeromonas hydrophila* or as pseudomonads.⁹⁵ Reports that *C. violaceum* infection causes a melioidosis-like illness were probably due to misidentification of *Burkholderia pseudomallei* by the API 20NE system.⁵¹

A clinical history of contamination of a wound with water or soil—especially in the southeastern United States or in Southeast Asia—with subsequent local infection, lymph node suppuration, and lack of response to conventional antibiotic therapy should arouse suspicion of *C. violaceum* infection. The clinician particularly should be aware of the possibility of *C. violaceum* infection in patients with CGD.

Treatment

C. violaceum is sensitive in vitro to chloramphenicol, gentamicin, fluorinated quinolones, tetracyclines, imipenem, trimethoprim-sulfamethoxazole, and semisynthetic penicillins. *C. violaceum* often is resistant to cephalosporins, penicillin, ampicillin, and the antistaphylococcal penicillins. All isolates are resistant to vancomycin and rifampin.⁵ Some strains have been shown to elaborate a β -lactamase, which is chromosomal and inducible in vitro.³² At least one case report gives in vivo evidence of inducible resistance to ceftazidime.¹⁰⁴ Laboratory evidence of susceptibility to erythromycin cannot be relied on. In vitro, the fluoroquinolones have the highest activity.⁵ Clinical experience with the fluoroquinolones in *C. violaceum* infection is scarce; an impressive case of a 4-month-old infant with severe disseminated *C. violaceum* infection who survived after therapy with trimethoprim-sulfamethoxazole and ciprofloxacin has been reported.⁷⁷ The review of 25 cases mentioned earlier found that all survivors had been given one or a combination of the following agents: ciprofloxacin, trimethoprim-sulfamethoxazole, chloramphenicol, or imipenem.⁹⁴

Because infection with *C. violaceum* is rare and often rapidly fatal, optimal antimicrobial therapy is unknown. Duration of therapy also is unknown, but because of late recurrences, some authors recommend 3 to 4 weeks of intravenous therapy followed by 1 month or more of oral trimethoprim-sulfamethoxazole.⁸⁵

PLESIOMONAS SHIGELLOIDES

Plesiomonas shigelloides is the only species of the genus *Plesiomonas*. These organisms are facultatively anaerobic, motile, gram-negative rods that are common inhabitants of surface water and fish. They have been

implicated in gastrointestinal infections and, rarely, have been recovered from extraintestinal sites.

Bacteriology

P. shigelloides is a member of the Vibrionaceae, although some authorities suggest that it is related more closely to Enterobacteriaceae.⁶⁶ The organisms are motile by means of a polar flagellum. They can produce lateral flagellae when grown in solid or semi-solid media.⁷⁴ They are lysine positive, ornithine positive, and arginine decarboxylase positive. They can be distinguished from Enterobacteriaceae by oxidase positivity. They also are catalase positive and indole positive. They grow well on MacConkey agar but not on thiosulfate citrate bile salts sucrose agar. Growth may be enhanced by the use of selective media, such as trypticase soy broth with ampicillin⁸⁶ and inositol brilliant green–bile salts agar. Growth is maximal at 40°C to 44°C and completely inhibited at 8°C. Usually within 24 hours, 1.0- to 1.5-mm grayish, shiny, opaque colonies with a slightly raised center and a smooth surface are visible. A few isolates of *P. shigelloides* share a common O antigen with *Shigella sonnei*.

Epidemiology

The organism is a ubiquitous freshwater inhabitant at temperatures greater than 8°C. It sometimes also is found in estuarial waters in temperate or tropical climates and can exist in seawater during the summer. It has been cultured from finfish, shellfish, pigs, birds, and dogs.¹⁰⁸ Although infection with *P. shigelloides* has been associated with ingestion of raw or improperly cooked fish (especially oysters), it is unknown what role, if any, other animals play in the ecology of the organism. Asymptomatic carriage of *P. shigelloides* is rare in developed countries⁹⁰ but may be 15% in some parts of China.¹⁰⁸

Pathophysiology

Despite the ubiquity of the organism in nature, human infection is uncommon. Most often, infection is associated with gastroenteritis. Evidence for the role of *P. shigelloides* in the production of gastrointestinal symptoms is that it has been isolated much more frequently from patients with diarrhea than from healthy control subjects⁴⁸; there have been some outbreaks, especially in Japan; it often is the only organism detected in the stools of patients with gastroenteritis⁷¹; and patients who have *P. shigelloides* growing from a stool culture recover more quickly with than without antibiotic therapy.⁵⁵ Acquisition of disease has been linked specifically to consumption of raw seafood or untreated water and to foreign travel, especially to Mexico.^{45,70} A study in China found *P. shigelloides* in 2.9% of 3564 outpatients with diarrhea; it accounted for 7.3% of bacterial isolates.²³

The mechanism by which the organism produces disease has been elusive. It is not enteroinvasive by laboratory tests, most investigators fail to find either a Shiga toxin or an enterotoxin,^{1,45} no animal model of gastrointestinal disease has been found,¹⁸ patients in the recovery phase do not show serologic evidence of infection, and inoculation of volunteers fails to produce illness.⁴⁵ In a suckling gnotobiotic piglet model in which the animals became septic, histology of the gastrointestinal tract showed neither destruction of cells nor invasion of tissues.⁴⁵ Neonatal BALB/c mice became chronically infected with *P. shigelloides*, however; histopathologic findings included some cases of necrosis of the mucosal surface of the ileum and colon.¹⁰⁷

Some potential virulence factors (i.e., a cholera-like toxin, a weak cytotoxin, serum resistance, and a large [>150 -kDa] plasmid) have been described, but their exact roles in pathophysiology are uncertain; attempts to correlate these features with virulence have been fruitless.¹ Investigators have characterized a cytotoxin derived from *P. shigelloides* using strains from patients with a diarrheal illness. The cytotoxin is a complex of three lipopolysaccharide-binding proteins and lipopolysaccharide in a 6:5 ratio.⁸¹ Cytotoxic activity was inhibited 80% in vitro by proteinase K or when incubated with anticholera toxin antibody. This cytotoxin produced a positive reaction in the suckling mouse assay, whereas the purified lipopolysaccharide exhibited almost no cytotoxicity.⁸¹ The lipopolysaccharide downregulates complement and has been shown to be important in attachment, invasion, and biofilm formation.¹⁴

Transmission electron microscopy has provided investigators with the first definitive proof that *P. shigelloides* can adhere to and invade

eukaryotic intestinal cells. Organisms attached to microvilli and plasma membranes of the cells; they also were seen within vacuoles in the cell cytoplasm, suggesting a phagocytotic entry mechanism.¹⁰² In one in vitro system using Caco-2 cells, adherence occurred within 10 minutes and internalization occurred within 60 minutes. Cytotoxicity was due to the induction of apoptosis.¹⁰⁵ In vitro, cell-free and cell-associated hemolysis is demonstrable,⁴⁰ and low levels of elastase, proteinase, histidine decarboxylase, and moderate levels of triacylglycerol lipase activity have been found.²⁶ Culture filtrates are capable of inducing vacuolation of a variety of mammalian cells in vitro.³¹

P. shigelloides rarely, but more clearly, is a pathogen in extraintestinal sites. Osteomyelitis, endophthalmitis, cholecystitis, pseudoappendicitis, spontaneous peritonitis,¹ meningitis,¹⁰¹ and septicemia have been reported sporadically.¹⁸ Most patients with septicemia have been immunocompromised hosts, but the organism has been isolated from blood cultures in otherwise healthy individuals.^{52,84} The mode of infection in extraintestinal sites is unclear, but most cases are thought to arise from the gastrointestinal tract. The case of a newborn with *P. shigelloides* meningitis, septicemia, and endophthalmitis who was born to a mother who reported severe diarrhea after eating raw oysters 2 weeks before delivery raises the possibility of transplacental transmission.⁶⁹

Clinical Manifestations

Patients with *P. shigelloides* gastroenteritis complain of diarrhea, crampy abdominal pain, nausea and vomiting, headache, and fever. Symptoms usually begin 24 hours to 4 days after contact with the organism.⁴⁸ Diarrhea tends to be secretory, although some patients have symptoms more consistent with colitis.⁵⁵ Passage of blood, mucus, or both in the stools is a common manifestation, as is the presence of white blood cells by Wright stain.⁴⁸ Patients with *P. shigelloides* gastroenteritis tend to have disease that is more acute, associated with more severe abdominal pain, and of longer duration than patients with diseases caused by other enteropathogens.⁵⁵

In one case-control study, 76% of patients were sick for more than 2 weeks and 32% were sick for more than a month.⁵⁵ In contrast, a large Japanese study of returning travelers suggested that for most patients, the symptoms abated within approximately 3 days.⁹³ In a series of 38 pediatric cases in Bangladesh, 84% had secretory diarrhea and 71% had associated emesis. Only three patients (8%) had fever, and only five (13%) had diarrhea for 14 days or longer.⁶⁰ In a separate report, one child developed migratory polyarthritides during an otherwise typical case of culture-proven gastrointestinal infection. All symptoms and signs of arthritis disappeared when the gastrointestinal infection was treated with antibiotics.⁴²

Localized extraintestinal infections have been reported but are rare. Two cases of severe polymicrobial endophthalmitis resulting from fishhook trauma progressed to enucleation.²² A rapidly progressive keratitis after corneal laceration has been reported.⁶¹ Two cases of peritonitis associated with continuous ambulatory peritoneal dialysis were reported from Hong Kong. Both patients recovered after 10 days of therapy with intraperitoneal cefazolin and tobramycin.¹⁰⁹ There has been one report of spontaneous bacterial peritonitis.⁸³ In one odd case, a woman had pyosalpinx from *P. shigelloides* thought to have been acquired by swimming in contaminated water.⁹¹ A cavity pneumonia was found in a 78-year-old woman who underwent gastrectomy and esophagojejunostomy because of adenocarcinoma of the stomach. Biopsy showed granulomatous changes.⁹² One patient developed a skin abscess after incurring trauma in fresh water.⁴⁶

Septicemia, meningitis, or both usually occur in immunocompromised hosts. Severe, rapidly progressive sepsis complicated by disseminated intravascular coagulation, adult respiratory distress syndrome, renal insufficiency, hepatic dysfunction, adrenal hemorrhage, and splenic abscess has occurred in patients with hemoglobinopathies and absence of splenic function, including thalassemia intermedia and sickle-cell disease.^{7,106} Unusual sites of infection sometimes are noted in immunocompromised individuals, such as epididymo-orchitis in a patient with human immunodeficiency virus infection.¹¹² Newborns constitute most of the reported cases of *P. shigelloides* meningitis, in whom the mortality rate is 80%.¹ Cerebrospinal fluid parameters may be normal, even when the culture is positive.⁸² Septicemia also has a

high mortality rate in adults, although otherwise well patients may recover with appropriate antimicrobial therapy.

Diagnosis

A clinical history of foreign travel or of ingestion of raw seafood or untreated water should raise suspicion of possible *P. shigelloides* infection, especially when the clinical illness matches the description just mentioned. Oxidase tests should be done on any predominant or solitary organisms to distinguish them from Enterobacteriaceae.⁴⁸ The organisms can be shown not to be aeromonads or pseudomonads by production of ornithine decarboxylase and fermentation of inositol. Selective medium can be used if the index of suspicion is high. A new indicator medium (UNISC agar) for the identification of *Aeromonas* and *Plesiomonas* has been developed; colonies turn yellow if xylose is fermented and turn blue if it is not.⁸⁹ Loop-mediated amplification assays⁷³ and polymerase chain reactions have also been developed; it is included in some commercial multiplex polymerase chain reactions that are increasingly available.

Treatment

Most strains of *P. shigelloides* produce a β -lactamase,⁸⁷ which seems to be specific for the penicillins. In one study, all isolates were resistant to ampicillin, ticarcillin, carbenicillin, and piperacillin.³⁷ *P. shigelloides* is universally susceptible to trimethoprim-sulfamethoxazole, the fluoroquinolones, most cephalosporins, carbapenems,⁹⁹ tetracycline,⁹⁹ and chloramphenicol. It is variably susceptible to the aminoglycosides and mostly resistant to erythromycin.⁵⁴

P. shigelloides gastroenteritis resolves without therapy, but the illness may be prolonged. Treatment seems to shorten the course.³⁵ Extraintestinal infections carry a poor prognosis and should be treated aggressively. For meningitis, cephalosporins and carbapenems have good cerebrospinal fluid penetration and are effective therapy against most isolates.

OTHER PASTEURILLA ORGANISMS

The genus *Pasteurella* consists of a group of pleomorphic, gram-negative coccobacilli that are part of the normal flora of many animals. These organisms are frequent animal pathogens. *P. multocida* is a common human pathogen and is discussed in Chapter 116. The other species of the genus *Pasteurella* are rare but occasionally cause serious infection in humans.

Bacteriology

These organisms, similar to *P. multocida*, grow readily on most common laboratory media, including blood agar. Most of the species do not grow on MacConkey agar. They are non-spore forming, nonmotile, aerobic, and facultatively anaerobic. These glucose-fermenting organisms all are oxidase positive. Most are nitrate positive and catalase positive, and all except *Avibacterium gallinarum* (formerly *Pasteurella gallinarum*, discussed later) produce indole. They are small, coccoid or rod-shaped bacilli that may show prominent bipolar staining on Gram stain. Colonies are small, translucent, and gray and may be smooth or rough. A browning discoloration may develop around them, and they are nonhemolytic with a distinctive musty or "mushroom" odor.²⁵

The taxonomy of these organisms is confusing and continues to be revised. *Pasteurella ureae* was moved to the genus *Actinobacillus*. *Pasteurella haemolytica* has been reclassified into the genus *Mannheimia*.⁹ *Pasteurella dagmatis* is the name now given to what formerly was called *P. new* species, or *P. "gas."*⁷⁸ *Pasteurella gallinarum*, *Pasteurella avium*, and *Pasteurella volantium* have 96.8% sequence similarity and are phenotypically separate from other *Pasteurella* spp.; therefore, they have been moved into the genus *Avibacterium*.¹⁷ Most experts agree that the genus *Pasteurella sensu stricto* should include *P. multocida*, *P. canis*, *P. stomatis*, and *P. dagmatis*.⁵⁶ *Pasteurella* spp. B has now been reclassified as *P. oralis* sp. nov.²⁴ Clinically recovered species other than *P. multocida* include *Actinobacillus ureae*, *Mannheimia haemolytica*, *Pasteurella pneumotropica*, *P. dagmatis*, *P. canis*, *Pasteurella aerogenes*, *Pasteurella bettyae*, *P. "SP"* group, *P. oralis*, and *P. stomatis*. *Pasteurella caballi* has caused wound infections after horse bites.²⁹ *Avibacterium gallinarum* is an extremely rare pathogen in humans.

Pathophysiology

Infection with *Pasteurella* spp. has been divided clinically into three types: (1) from animal bites, (2) from animal contact,³⁶ and (3) without known animal contact.²⁷ Infections from animal bites include cellulitis, abscesses, tenosynovitis, and bone and joint infection, but infection can become generalized, especially in patients who are immunocompromised. Infections caused by animal contact can be similar to infections described earlier and are caused by animals licking broken skin or wounds. Sometimes pulmonary infections occur, possibly related to aerosolization of organisms. In some cases, these organisms have been reported as respiratory flora in patients with pets, but at present no proof exists that such colonization is an antecedent of infection.³⁴ Cases without known animal contact history constitute 3% to 30% of all cases.^{49,53}

Infection usually occurs when the organisms are inoculated into deeper tissues either on animal teeth that break the skin or in animal saliva that comes in contact with nonintact skin. Bite wound infections often are polymicrobial. Infection in cases without known animal contact is harder to explain but definitely happens.⁵⁷ Most cases of serious infection occur in patients with underlying diseases, such as diabetes mellitus, chronic alcoholism, and other types of liver disease.⁸⁰ Central nervous system infection with these organisms has occurred after head trauma or neurosurgery in 10 of 11 reported cases.⁵⁷ One intrauterine death of the fetus of a 20-year-old woman who worked at a pig farm has been attributed to *P. aerogenes*.¹⁰³ Case reports of unusual infections with rare species of *Pasteurella*, such as fatal sepsis and meningitis in a 4-day-old infant caused by *A. gallinarum*,² should be considered doubtful unless molecular identification methods have been used.⁴⁴

Clinical Manifestations

Pasteurella infections produce pain, swelling, pus, and sometimes abscess formation at the site of inoculation, beginning within 24 to 36 hours. Clinically, these infections are indistinguishable from wound infections with *Staphylococcus aureus* or other gram-positive organisms. Gram stain may show the characteristic pleomorphic bacilli with bipolar staining. Growth on standard agar is rapid.

Patients with peritonitis,^{4,80} meningitis,⁵⁷ osteomyelitis,³⁷ or infectious endocarditis⁶ have symptoms typical of these diagnoses. Risk factors—such as household pet exposure, animal contact, animal bites, and comorbid conditions—should heighten suspicion of possible *Pasteurella* infection. One report describes a previously healthy 21-month-old girl who developed *P. canis* bacteremia after exposure to rabbit saliva.¹¹¹ Bacteremia due to *P. canis* has also been described in a cirrhotic patient whose leg wound was licked by a dog.³ Children on continuous ambulatory peritoneal dialysis may rarely develop peritonitis with *Pasteurella* species.⁴¹

In one eastern European study of an outbreak in a child welfare agency, *P. canis* was cultured from the anterior fornix of several infants with refractory conjunctivitis.¹⁵

Diagnosis

Establishing the diagnosis of *Pasteurella* infection can be difficult, not because the organism is fastidious or slow growing but because it often is misidentified. Other organisms of the same family (i.e., *Actinobacillus* spp. and *Haemophilus* spp.) have similar biochemical profiles and can be misidentified by commonly used systems, such as API. Lester and associates⁶⁴ reported that of 30 species firmly identified as *Pasteurella* by biochemical means, only 3 were identified correctly by the API 20E system. *Actinobacillus (Haemophilus) aphrophilus* and *Actinobacillus actinomycetemcomitans* are sometimes misidentified as *Avibacterium gallinarum* by commercial systems.³⁵ Additionally, Hamilton-Miller⁴³ reported that four strains of *Haemophilus influenzae* and three strains of *Haemophilus parainfluenzae* were identified falsely as *Pasteurella* spp. by API and suggested that if the clinical history renders *Pasteurella* infection unlikely, then tests for X and V factor requirements should be performed (see Chapter 133). Clinical case reports corroborate these laboratory observations.^{30,80,97} Notifying the bacteriology laboratory of suspicion of *Pasteurella* infection is helpful. These problems are being

minimized by newer techniques, including matrix-assisted laser desorption ionization-time of flight.

Treatment

Penicillin has been considered the drug of choice for *Pasteurella* infection in the past and, despite some reports of penicillin resistance, still is effective against most strains. *Pasteurella* spp. also are susceptible to ampicillin, β -lactamase-inhibitor combination drugs, tetracycline, and chloramphenicol. Truncated but fully functional tetracycline resistance genes have been identified in isolates from animal sources.⁵⁹ The aminoglycosides, erythromycin, clindamycin, cefadroxil, and cefaclor are not recommended. Dicloxacillin and cephalixin have poor activity against *Pasteurella* spp. and should not be used as monotherapy for animal bite wounds.³⁸ In one study of bite wound infections, ertapenem was found to be active against all *Pasteurella* spp.³⁹ Of fluoroquinolones tested in vitro against 75 clinical isolates of *Pasteurella* spp., levofloxacin was the most active.⁴⁷

Acknowledgments

I thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

Acinetobacter

Armando G. Correa

First recognized as a human pathogen in 1908,⁹⁴ the ubiquitous organism *Acinetobacter* has emerged as a rather common cause of health care–associated infections in immunocompromised hosts.⁸ Some of the confusion regarding this organism may be attributed to the many changes in nomenclature that the members of this genus have undergone over the years. Names used in the past to identify this genus include *Herellea*, *Bacterium*, *Mima*, *Achromobacter*, *Alcaligenes*, *Neisseria*, *Micrococcus*, *Diplococcus*, *Moraxella*, and *Cytophaga*. Treatment of infection caused by *Acinetobacter* is complicated by its widespread multidrug resistance and the difficulty encountered in eradicating the organism.

ORGANISM

The genus *Acinetobacter* is now classified in the Moraxellaceae, a recently proposed family that also includes the *Moraxella* and *Psychrobacter* genera.⁶⁵ *Acinetobacter* is a gram-negative bacterium that typically appears as a rod 0.9 to 1.6 μm in diameter and 1.5 to 2.5 μm in length, but it may become spherical in the stationary phase of growth. It frequently occurs in pairs or short chains. Many strains are encapsulated. The organism has a strictly aerobic respiratory metabolism and does not grow under anaerobic conditions. It does not form spores or exhibit swimming mobility. *Acinetobacter* grows well in all common complex media between 20°C and 30°C, with optimal growth occurring between 33°C and 35°C, and it has no growth factor requirements.

Convex, grayish white colonies 1.0 to 2.5 mm in diameter are typical findings. The colonies may appear mucoid if the strain is encapsulated. *Acinetobacter* is catalase positive and may be differentiated readily from other closely related genera by virtue of its negative reaction to oxidase.

Formerly, the genus *Acinetobacter* contained the single species *A. calcoaceticus* subdivided into two subspecies or biovars: *anitratus* and *lwoffii*.⁴² However, in 1986, the taxonomy of the genus *Acinetobacter* was changed extensively on the basis of DNA hybridization studies,¹³ and at least 46 genomic species have been proposed, of which 41 have been assigned species names, according to the list of prokaryotic names with standing nomenclature (www.bacterio.net, as of June 2016). At least 19 of these nomenspecies have been isolated from human specimens, including: *A. baumannii*, *A. calcoaceticus*, *A. haemolyticus*, *A. johnsonii*, *A. junii*, *A. lwoffii*, *A. radioresistens*, *A. parvus*, *A. schindleri*, and *A. ursingi*.^{20,42,59,60} Several genospecies that have been isolated from human clinical samples and had been given the provisional designation of genomic species 3, 13TU, 10, and 11 have now been named as *A. pittii*, *A. nosocomialis*, *A. bereziniae*, and *A. guillouiae*, respectively.^{59,60} *A. soli*, a species previously isolated only from soil, has recently been implicated in an outbreak in a neonatal care unit.⁶⁶ Newly named species that have recently been isolated for human samples include *A. beijerinckii*, *A. gyllenbergii*, *A. seifertii*, and *A. variabilis*. These species may be difficult to differentiate in the clinical laboratory on the basis of their growth characteristics and biochemical activity.^{43,65} In light of their closely related phenotypic properties and antimicrobial resistance, four of these species, *A. baumannii*, *A. calcoaceticus*, *A. pittii* (formerly genomic species 3), and *A. nosocomialis* (formerly genomic species 13TU), are grouped under the term *A. baumannii-calcoaceticus* complex. Furthermore the three clinically relevant members of this complex (*A. baumannii*, *A. pittii*, and *A. nosocomialis*) cannot be separated by currently available commercial identification systems, prompting the use of the term *A. baumannii* group to accommodate these three species that share epidemiologic and clinical features.^{42,65} Under the new classification, most

HCW, Health care workers; NA, data not available; NICU, neonatal intensive care unit; PICU, pediatric intensive care unit.

^aOutbreak was due to imipenem-resistant *A. baumannii*.

A. baumannii strains represent organisms that were classified formerly as biovar *anitratus*, whereas *A. junii* and *A. lwoffii* previously were listed under the biovar *lwoffii*.

EPIDEMIOLOGY

Acinetobacter strains are distributed widely in nature and can be found in soil, fresh water, and sewage.^{10,33} *Acinetobacter* also can be isolated from many animals, fresh meats, poultry, contaminated milk, and frozen foods.^{10,33} The organism can be part of the bacterial flora of the skin in healthy individuals,^{10,15} and the skin frequently becomes a reservoir for *Acinetobacter* in hospitalized patients and the health care staff.^{8,10} It occasionally forms part of the normal flora of the oral cavity and the upper respiratory, genital, and lower gastrointestinal tracts.^{10,15} Colonization by *Acinetobacter* is particularly common in patients who have undergone a tracheostomy.⁷³ The organism frequently can be found in the hospital environment, particularly in moist areas, such as in humidifiers, water sinks, and ventilators.¹⁰ In an outbreak of bacteremia due to *A. junii* among children in a pediatric oncology ward, faucet aerators were found to be reservoirs.⁴⁴ Nosocomial outbreaks have been linked to colonized medical equipment such as ventilator tubing and other respiratory equipment,³¹ intravenous catheters,¹⁰ hygroscopic bandages,⁸⁷ gloves,⁶⁴ and mattresses.⁸⁴

The frequency of occurrence of health care–associated infections by *Acinetobacter* is not easy to assess because the pathogenic role of this organism often has been underestimated. However a national surveillance study conducted from 1974 to 1977 identified *Acinetobacter* as a pathogen in 0.76% of nosocomial infections.⁷² The estimated rate of health care–associated infections caused by this organism was 3.11 per 10,000 patients discharged, and approximately 15% of 1372 reported episodes occurred in the pediatric age group.⁷² By 1978, this rate increased by 14% and accounted for 1% of the bacterial isolates associated with healthcare-associated infections.¹⁵ An unusual seasonal pattern was observed, with most infections occurring in late summer.^{15,72} The cause of this increase is unknown. In a national prospective survey of US hospitals from 1995 through 2002, *Acinetobacter* spp. accounted for 1.3% of all health care–associated bloodstream infections and was associated with a crude mortality rate of 34%.⁹⁸ By 2003, the percentage almost doubled to 2.4% of nosocomial bloodstream infections from the same surveillance system.²⁶ When comparing data from 1986 to 2003, *Acinetobacter* spp. were the only gram-negative pathogens associated with a consistently increasing proportion of hospital-acquired pneumonias, as well as surgical site, urinary tract, and bloodstream infections.²⁶ Between 2006 and 2007, *A. baumannii* was the ninth most common

pathogen associated with cases of health care–associated infections, accounting for nearly 3% of them.³⁵

Data from SENTRY, an international surveillance program that monitors the frequency of occurrence and antimicrobial susceptibility of bacterial pathogens, revealed a significantly greater frequency of *Acinetobacter* infections in Latin America than in all other regions.²⁵ Data from another international surveillance consortium study of ICU infections from 2003 to 2008 revealed a striking increase in frequency of resistance to imipenem among *A. baumannii* when compared to that reported in a similar US system (46% vs. 29%).⁷⁶ A higher prevalence rate of *Acinetobacter* infections was noted in patients ranging in age from birth to 10 years.²⁵ In the pediatric age group, at least 20 outbreaks of invasive nosocomial infections due to *Acinetobacter* have been reported in the past three decades^{37,38,87}; the vast majority of them were concentrated in neonatal ICUs (Table 121.1).^{38,58,87}

More recently, *Acinetobacter* emerged as a particularly important pathogen in unusual situations such as earthquakes and war zones.⁴¹ This prevalence was illustrated by reports of outbreaks of multidrug-resistant *Acinetobacter* infections associated with the US-Iraq conflict.⁸¹

PATHOGENESIS

Limited information is available regarding the pathogenesis of *Acinetobacter* infections. The lipopolysaccharide of *Acinetobacter*, a normal constituent of the outer membrane of gram-negative bacteria, is capable of eliciting multiple pathogenic host responses. Strains producing exopolysaccharide have been shown to be more pathogenic than are nonproducers.⁴¹ Nonspecific adherence factors, such as fimbriae, also have been described in *Acinetobacter*.⁴¹ The role of quorum sensing as a regulatory mechanism for autoinduction of multiple virulence factors in *Acinetobacter* is under investigation.⁴¹

In animal models, *Acinetobacter* can enhance the virulence of other bacteria in mixed infections, perhaps by slime-induced inhibition of neutrophils.⁶² Researchers have speculated that the ability of this organism to grow in an acidic pH at lower temperatures may enhance its ability to invade devitalized tissue.² The organism also may survive in a dry environment for as long as a week.¹⁶

CLINICAL MANIFESTATIONS

Acinetobacter can cause suppurative infection of virtually any organ, and the clinical manifestations typically are similar to those seen with other bacterial infections because no unique features are suggestive of *Acinetobacter* infection. The clinical manifestations also may depend

on the underlying immune status of compromised hosts. Infections caused by *Acinetobacter* are rare occurrences in normal children²¹ and have mostly occurred in tropical areas.

Intracranial Infection

Most cases of *Acinetobacter* meningitis are the result of a penetrating injury or occur after a neurosurgical procedure, although sporadic cases of meningitis have been reported in the absence of these factors. A cluster of eight children in whom *Acinetobacter* meningitis developed after the administration of intrathecal methotrexate was reported.⁴⁴ All patients had fever, headache, nausea, and vomiting; and lumbar puncture revealed cerebrospinal fluid (CSF) pleocytosis.

The earlier literature contains several reports of *Acinetobacter* meningitis developing in apparently normal children.^{18,19,34,91,95} CSF pleocytosis with a predominance of segmented forms occurred commonly.¹⁹ Because as many as 30% of these patients had a petechial rash and gram-negative diplococci on CSF smears, the diagnosis of meningococcal meningitis was made erroneously in most of these cases, thereby leading to a delay in the institution of appropriate therapy and possibly contributing to a mortality rate as high as 27%.¹⁹

Siegmán-Igra and associates,⁸⁶ in a review of 25 cases of *Acinetobacter* meningitis secondary to invasive procedures that included some children, found that fever, leukocytosis, and neck stiffness, along with other clinical signs of central nervous system (CNS) infection, were common features. The CSF in these patients showed pleocytosis with a predominance of polymorphonuclear leukocytes, elevated protein concentration, and a low glucose level. Most of the infections were associated with indwelling ventriculostomy tubes or a fistula into the CSF space. A case series from Pakistan⁷⁸ reported eight cases of *Acinetobacter* meningitis that occurred over the course of a 4-year period in children who had undergone neurosurgical procedures. Mortality in this series was 25%, and the use of intrathecal antibiotics was explored as an adjunctive therapy.⁷⁸

Researchers have suggested that an inherited or acquired complement deficiency may be associated with meningitis caused by *Acinetobacter*²³ because it is seen with *Neisseria meningitidis* and other related species. Treatment of CNS infections caused by *Acinetobacter* requires a minimum of 3 weeks of parenteral antibiotics.

Bacteremia

Acinetobacter bacteremia may occur as an isolated event or may be secondary to a primary infected site, such as the respiratory tract, urinary tract, or a wound. Primary bacteremia appears to occur more commonly in immunocompromised neonates, and clinical manifestations can vary from an absence of clinical signs of infection to fulminant septic shock and disseminated intravascular coagulation.^{46,80} Thrombocytopenia has been reported to be a prominent feature in these neonates.^{39,61,71} Pneumonia has been seen more commonly in early-onset sepsis.⁵⁶ Predisposing factors include low birth weight,^{77,80} previous antibiotic therapy,^{71,77,80} and the presence of indwelling catheters.^{39,55,77}

Acinetobacter bacteremia in children with malignant diseases also has been noted to occur rarely. Fuchs and colleagues²⁴ reported 29 episodes of sepsis caused by this organism over the course of a 12-year period in an oncology center. All these children were febrile and appeared ill at the time of diagnosis, and a high association of *Acinetobacter* sepsis with the presence of intravascular catheters was noted. Surprisingly no connection was found with the level of neutropenia.²⁴

Community-acquired *Acinetobacter* bacteremia among infants less than 2 months of age has been reported in some developing countries.³⁰

Respiratory Tract Infections

Because *Acinetobacter* may be a transient colonizer of the pharynx in 7% of healthy children⁷ and adults²⁷ and this rate is increased in hospitalized patients, the relative importance of *Acinetobacter* in comparison with other potential pathogens isolated from sputum is difficult to ascertain. The tracheobronchitis and pneumonia attributed to *Acinetobacter* are mostly nosocomial infections associated with the presence of an endotracheal tube or tracheostomy.²⁷ Pneumonias frequently are multilobar and occasionally may lead to cavitory destruction or pleural empyema.²⁷

Community-acquired pneumonia caused by *A. baumannii* has been reported to occur in adults in the Northern Territory of Australia and other tropical regions.⁵ This entity generally is seen in patients with diminished host defenses caused by alcoholism, cigarette smoking, or underlying pulmonary disease and is characterized by the rapid onset of fever, dyspnea, pleuritic chest pain, and purulent sputum. The mortality rate has been as high as 53% to 64%,⁵ although increased awareness and implementation of empiric antibiotic protocols that cover this organism has led to a dramatic reduction in mortality in these regions.¹⁷ A case of necrotizing pneumonia due to *A. lwoffii* in a previously healthy toddler has been reported.⁵⁷

Miscellaneous Infections

Urinary tract infections occur almost exclusively in patients with indwelling bladder catheters, usually are limited to the bladder, and generally are mild.²⁷ Burns, as well as traumatic and surgical wounds, frequently become colonized by *Acinetobacter* as a result of the ability of this organism to thrive on compromised tissue and foreign material.²⁷ Bacteremia may occur as a consequence of this colonization, which is often polymicrobial. *Acinetobacter* is a prominent cause of peritonitis in children undergoing peritoneal dialysis when gram-negative organisms are involved.⁹⁶

Other rare infections caused by *Acinetobacter* that have been reported include suppurative otitis media,^{73,91} cellulitis (frequently in association with trauma, a foreign body, or an animal bite),^{27,73} synergistic necrotizing fasciitis,⁴ native-valve and prosthetic-valve endocarditis,²⁹ septic arthritis,⁷³ osteomyelitis,⁹¹ and liver abscesses.²⁷ Ocular infections also have been documented.⁵³ A case of osteomyelitis occurring after a hamster bite in a child has been described.⁵⁴

DIAGNOSIS

The diagnosis of *Acinetobacter* infection is made by culture of appropriate body fluids or tissue specimens. No serologic or antigen-detection tests are available. A selective medium containing MacConkey agar with cephaloridine has been used to culture skin specimens during investigation of outbreaks⁸⁸ because of its ability to inhibit most of the skin flora but not *Acinetobacter*.

Biotyping, phage typing, electrophoretic analysis of isoenzyme and cell wall proteins, plasmid analysis, polymerase chain reaction–based DNA fingerprinting, and restriction endonuclease digestion of DNA have been used for investigation of nosocomial outbreaks.^{9,65} Antibigram typing no longer is considered an effective method in the investigation of *Acinetobacter* epidemics because the susceptibility pattern may change rapidly within the same outbreak.^{9,14}

TREATMENT

As with many other opportunistic gram-negative organisms, treatment of infections caused by *Acinetobacter* spp., particularly those of the *A. baumannii* group,^{82,93} has become more complicated by the rapid increase in resistance to the antibiotics used commonly in hospitals. Selection of an antibiotic regimen should be based on in vitro susceptibility testing and ideally should include both a β -lactam antibiotic and an aminoglycoside, which may have synergistic activity²⁷ and prevent the emergence of resistance.⁸

Species of the *A. baumannii-calcoaceticus* complex have shown decreased susceptibility to ampicillin, broad-spectrum penicillins, cephalosporins, aminoglycosides, and ciprofloxacin.^{25,82} Resistance to extended-spectrum cephalosporins may be the result of the presence of cephalosporinases (particularly the chromosomally encoded cephalosporinase AmpC),¹² other broad-spectrum β -lactamases, or changes in the outer-membrane porins and penicillin-binding proteins.^{12,63} Resistance to aminoglycosides is mediated by aminoglycoside-modifying enzymes.⁹³ The carbapenems imipenem and meropenem appear to be the most active agents against *A. baumannii*,^{86,93} but reports have found more than 10% of such strains to be resistant to these antibiotics in some areas,^{25,52} and increasing numbers of nosocomial outbreaks of carbapenem-resistant *Acinetobacter* infections have been reported.^{28,65,92,100} The incidence of carbapenem-resistant *Acinetobacter* strains has been

particularly high in Latin America, Africa, Europe, and the Asian Pacific rim region.^{11,25,51} Resistance to the carbapenems has been associated with the presence of serine and metallo- β -lactamases (carbapenemases). Of particular concern are the numerous carbapenem-hydrolyzing OXA enzymes that have emerged in *A. baumannii*.¹² Caution should be exercised when using imipenem in high doses in children for the treatment of meningitis (i.e., 100 mg/kg per day) because of an unusually high rate of seizures.⁹⁹ Thus, meropenem is recommended for this indication. Doripenem, a newer carbapenem antibiotic, has more potent in vitro activity against *Acinetobacter* species compared with other carbapenems,²² but its safety and effectiveness in pediatric patients have not been established. On the other hand, ertapenem has poor in vitro activity against *Acinetobacter*⁴⁹ and should not be used for the treatment of these infections. Combinations of a β -lactam antibiotic with a β -lactamase inhibitor, such as ampicillin-sulbactam, piperacillin-tazobactam, or ticarcillin-clavulanate, have been used for infections caused by carbapenem-resistant strains.^{92,100}

The fluoroquinolones, in particular ciprofloxacin, have been used successfully to treat infections caused by multidrug-resistant *Acinetobacter* in children^{56,67} and adults. Although ciprofloxacin has been approved for the treatment of complicated urinary tract infections in children and levofloxacin for postexposure treatment of inhalation anthrax in the pediatric age group, the other systemic fluoroquinolones are not approved for use in children younger than 16 years because of the theoretic concern for damage to growth cartilage. Of the quinolones, gatifloxacin exhibits the best in vitro activity against *A. baumannii*, followed by levofloxacin and trovafloxacin.³² Although 76% to 86% of sporadic isolates of *A. baumannii* are susceptible to the fluoroquinolones, only 32% to 55% of outbreak-related strains remain susceptible to this antibiotic class.³² Topoisomerase mutations in both *gyrA* and *parC* have been identified in quinolone-resistant *A. baumannii*.¹²

In some cases, the polymyxin drugs polymyxin B and colistin are the only therapeutic options for the treatment of multidrug-resistant *Acinetobacter* infection.^{28,48,85} Unfortunately with the increase in the use of colistin to treat these infections, the emergence of colistin-resistant *A. baumannii* has surged, particularly among patients who had previously received colistin for treatment of carbapenem-resistant, colistin-susceptible *A. baumannii*.⁷⁰ Efflux pumps capable of conferring resistance to multiple antibiotic classes have been identified in *Acinetobacter* spp.^{12,51,74}

Tigecycline is the first member of the glycylcycline antimicrobial class to gain approval in the United States. Because this agent demonstrates in vitro activity against multidrug-resistant strains of *A. baumannii*, its potential use as an alternative therapy for severe infections caused by this organism is being investigated.⁷⁴ However an increase in all-cause mortality observed in a meta-analysis of clinical trials in tigecycline-treated patients has prompted a warning to reserve its use to situations where alternative treatments are not available.⁶⁸ Data regarding the use of this agent in pediatric patients are lacking, and it should not be used in children unless no alternative agents are available.⁴⁰ In such circumstances, the suggested tigecycline dose for children 8 to 11 years is 1.2 mg/kg every 12 hours (maximum of 50 mg every 12 hours), and those 12 to 17 years should receive 50 mg every 12 hours.^{69,89} The development of resistance to tigecycline among clinical isolates of *Acinetobacter* has been documented and appears to be increasing in some regions.^{3,51}

Recently two novel combinations of a cephalosporin with a β -lactamase inhibitor, ceftazidime/tazobactam and ceftazidime/avibactam, gained approval in the United States for the treatment of complicated gram-negative infections in adults.⁸⁹ Although the former has shown good in vitro activity against *A. baumannii*,⁸⁹ there is no clinical data on its efficacy in the treatment of infections due to this organism. On the other hand, the addition of avibactam to ceftazidime does not appear to enhance activity against *A. baumannii* despite having action against carbapenemases.^{47,89} Safety and efficacy of these drug combinations in the pediatric population have not been established.

Lack of suitable options and efficacy data has made the treatment of multidrug-resistant *A. baumannii* infections a difficult task.⁸⁹ Based on limited in vitro and animal models data, it appears that combinations of antibiotics may be superior than single-agent regimens against carbapenem-resistant *A. baumannii*,^{65,89} such as polymyxin plus

rifampicin, colistin plus tigecycline, or two- or three-drug combinations with carbapenem plus rifampicin and/or sulbactam.^{65,89}

Imipenem, meropenem, amikacin, ciprofloxacin, ceftazidime, and ceftriaxone have exhibited good in vitro activity against isolates identified as species other than the *A. baumannii*-*calcoaceticus* complex.⁸² In addition to antimicrobial therapy, prompt drainage of focal suppurative sites and removal of infected indwelling catheters are essential. Intraventricular administration of amikacin, polymyxin B, or colistin has been used in the treatment of CNS infections caused by this organism.^{78,97} Similarly the use of adjunctive aerosolized therapy with colistin or tobramycin has been explored in adults with pulmonary infections.⁶

PROGNOSIS

Because *Acinetobacter* strains often are resistant to the antibiotics used commonly, prompt recognition of the specific cause and institution of effective antibiotic therapy are critical to achieving a successful outcome. The reported mortality rate in a series of pediatric patients ranged from 0% to more than 50% (see Table 121.1), and the outcome appeared to correlate more closely with the underlying condition than with other factors such as polymicrobial bacteremia.⁹⁰ In a series of 58 infections caused by this organism that occurred over the course of a 2-year period from 1973 through 1974 at the Massachusetts General Hospital in Boston, the mortality rate was 23%.²⁷ A 1999 prospective study in the Slovak Republic revealed that the case-fatality rate for 157 episodes of *A. baumannii* bacteremia was significantly higher in adults than in children (34% vs. 12%).⁴⁶ A recent systematic review that included a total of 469 children from 51 outbreaks and case series of invasive *Acinetobacter* infections revealed an attributable mortality of 14.5%.³⁸

The nosocomial acquisition of multidrug-resistant *A. baumannii* group has been associated with high mortality rates and prolonged hospitalization in adult patients in ICUs,^{50,79} in contrast to the more benign clinical outcome usually seen with other species of *Acinetobacter*.⁸³ Mortality rates as high as 85% have been reported in outbreaks of imipenem-resistant *A. baumannii* infection among pediatric patients.³⁶

PREVENTION

Nosocomial acquisition of *Acinetobacter* by high-risk compromised hosts can be prevented by placing emphasis on the control measures routinely used for endemic infections, such as careful hand washing by personnel, limitation of the frequency and duration of use of devices, proper isolation of colonized and infected patients, application of strict techniques for invasive procedures, restricted use of antibiotics, and implementation of antibiotic stewardship programs.^{16,50,51,87}

Achromobacter (Alcaligenes)

Randall G. Fisher

Organisms of the genus *Achromobacter* are gram-negative bacilli that live in aqueous environments. Originally considered commensals, they increasingly are recognized as important, although rare, hospital pathogens. *Achromobacter* can be especially problematic in immunocompromised patients and in neonates, in whom infection can be life-threatening. These organisms have been isolated from such diverse clinical specimens as sputum, urine, feces, blood, cerebrospinal fluid, cornea, and peritoneal and pleural fluids.

BACTERIOLOGY

Achromobacter spp. are gram-negative, motile, indole-negative, obligate aerobes that are oxidase and catalase positive. They are considered to be nonfermenters because of their extremely limited action on carbohydrates. Most ferment xylose, and some ferment glucose. All reduce nitrate to nitrite. They are urease, lysine, and ornithine negative. They grow well on both blood and MacConkey agar and produce colonies that are smooth and glistening and have a distinct edge. *Achromobacter* spp. alkalize organic salts and amides, a property that led to the name *Alcaligenes*, which means *alkali producing*. *Alcaligenes faecalis* has a distinct, sweet odor that has been described as resembling that of green apples.³²

Bacteriologically, these bacilli may be confused with other nonfermenting gram-negative organisms, especially *Pseudomonas* spp. Morphologically, however, they can be distinguished easily from pseudomonads by the presence of peritrichous flagella: *Pseudomonas* spp. have polar flagella.²⁷

The taxonomy of these organisms is confusing and undergoes frequent changes. They were classified as *Achromobacter* spp., then reclassified as *Alcaligenes*, and have been reassigned the name *Achromobacter*. The genera *Achromobacter* and *Alcaligenes* are closely related and comprise many species, but clinically important ones are as follows: (1) *Achromobacter xylosoxidans*, which has two subspecies: *xylosoxidans* and *dentrificans*, the former of which is the most common cause of clinically recognizable infection; (2) *A. faecalis*, which is a less common pathogen but has a distinct antimicrobial susceptibility pattern⁶; (3) *Achromobacter piechaudii*, which has been isolated from clinical specimens⁴⁹ but is of doubtful significance, and (4) *A. dentrificans*, which is a rare pathogen.⁵⁷ In the discussion that follows, the abbreviation *A. xylosoxidans* refers to *Achromobacter xylosoxidans* subspecies *xylosoxidans*.

EPIDEMIOLOGY

Like *Pseudomonas* spp., *Achromobacter* are water organisms and prefer aqueous environments and moist soil. They do not survive long on porous surfaces or fomites or if they become desiccated.⁵⁵ They also may be part of the normal flora of the ear and of the gastrointestinal

and respiratory tracts of some people. These organisms establish a niche within the hospital environment and have been recovered from ventilators, humidifiers, “sterile” saline, intravenous fluids, and irrigation and dialysis solutions. *Achromobacter* spp. also have been recovered from infant formula,²⁰ children’s soap bubbles,⁴² well water,⁶² and swimming pools.²⁹ Organisms also survive many disinfectants and have been cultured from chlorhexidine,⁵⁹ 1% eosin,⁷ and alcohol- or quaternary amine-containing compounds.^{55,59} Shigeta and associates⁵⁹ reported an outbreak of *A. xylosoxidans* ventriculitis secondary to contaminated chlorhexidine used on a surgical ward. Foley and colleagues²³ reported an outbreak accompanied by deaths in a neonatal intensive care unit (NICU) secondary to contamination of saline used as an eyewash. Boukadida and coworkers⁷ reported a neonatal death caused by meningitis contracted by dissemination after treatment of a diaper rash with 1% eosin. An outbreak of 37 cases (with two fatalities) that was caused by bacterial contamination of deionized water in a hemodialysis system was described by Reverdy and associates.⁵⁰ Surgical wound infection also has occurred in which infection was suspected to be secondary to contaminated irrigation fluids used in surgery.⁷¹ One outbreak of four cases in a hemodialysis unit was linked to an atomizer of 2.5% chlorhexidine used to disinfect the skin.⁶⁵ Three kinds of pseudo-outbreaks have been described: in one, seven patients in a pediatric hospital were infected with *A. xylosoxidans*, but restriction fragment-length polymorphism analysis proved they all were genetically unrelated⁵; in another, *A. xylosoxidans* was isolated from three different clinical specimens but was later proved to be a contaminant of the saline used in their processing²⁶; in a third, blood cultures were positive when drawn on the night shift because the nurses were cleaning the top of the blood culture bottles with a contaminated disinfectant.⁶¹

Studies have documented that *A. xylosoxidans* colonization of patients with cystic fibrosis (CF) is on the rise. In one large study, *A. xylosoxidans* was isolated from the sputum culture of 52 of 595 patients (8.7%).⁸ In other studies, isolates of *A. xylosoxidans* at a single CF center were not genetically related, a finding implying no common source of infection and little or no patient-to-patient spread within the center.^{18,70} However colonization of multiple patients with identical strains also is well documented.⁵³ Colonization rates as high as 17.6% have been reported; many of these patients were shown to be chronically colonized.³⁴ Molecular methods prove that other species of *Achromobacter* are also colonizers in CF patients, including *A. ruhlandii*, *A. insuavis*, and *A. dolens*.¹¹ In one study, all less common *Achromobacter* species were misidentified as *A. xylosoxidans* by matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF).⁵² Other investigators have reported 75% concordance between MALDI-TOF and 16SrDNA sequencing, however.³⁰ Most investigators report no significant changes in forced expiratory volume in 1 second (FEV₁) or growth parameters in *A. xylosoxidans*-colonized patients,³⁴ and the presence of pan-resistant

Keywords

Achromobacter

alcaligenes

gram-negative bacilli

A. xylosoxidans had no influence on survival after lung transplantation.³⁸ Environmental cultures at one CF center were positive for *A. xylosoxidans* only 0.8% of the time, whereas 22.8% of such cultures were positive for *Pseudomonas aeruginosa*.²²

PATHOPHYSIOLOGY

Achromobacter spp. are weakly virulent bacteria. Medical care commonly provides the conduit through which organisms are introduced into their host by way of indwelling catheters, endotracheal tubes, and so forth. The bacteria may take advantage of a weakened immune system and disseminate, causing sepsis, meningitis, and death. Preterm or term infants who are small for gestational age are at particular risk for acquiring such severe *Achromobacter* infections.²³ Although most neonatal infections are considered to be nosocomial, vertical transmission from mother to baby may occur.²⁷ An increased incidence of infection has been reported for patients with neoplasms³⁵ and those receiving long-term steroid therapy.³¹ Sporadic cases of *Achromobacter* infection in patients with idiopathic immunoglobulin (Ig)M deficiency,¹⁹ Waldenström macroglobulinemia,⁶⁴ granulomatosis with polyangiitis (Wegener granulomatosis),⁴⁸ and systemic lupus erythematosus have been reported.⁵⁴ My colleagues and I have seen one boy with hyper-IgM syndrome in whom 14 separate episodes of *Achromobacter* bacteremia occurred; an exhaustive environmental search for a source was fruitless. The source was eventually proved to be deep infection of a cervical lymph node, and the episodes ceased when the node was removed.⁷² *Achromobacter* infections occur in patients with acquired immunodeficiency syndrome (AIDS),^{10,25} but whether this syndrome is an independent risk factor for infection is unclear.

In one study, patients with CF and colonized with *A. xylosoxidans* tended to be older (mean age, 20 years) and at baseline had worse lung function than did uncolonized controls; however, over the course of the study, the rate of decline of lung function did not differ between cases and controls.¹³ In a second similar case-control study, lung function decline and growth parameters generally were not affected by colonization; however a subset of patients had rapidly increasing antibody titers against *A. xylosoxidans*, and this group did experience more accelerated decline.⁵³

In unusual circumstances, patients with neither overt underlying disease nor obvious immune deficiency will develop infection with *Achromobacter* spp. Most of these cases involve penetrating trauma. One case of corneal infection complicating epidemic keratoconjunctivitis in a normal host has been described.⁴⁴ Eye infections, including conjunctivitis and keratitis, also have occurred in patients who wear contact lenses; the organism was also recovered from contact lens cases and solutions.^{33,39} Post-LASIK *A. xylosoxidans* keratitis can be misdiagnosed as recurrent corneal erosion owing to a lack of signs suggesting acute inflammation.⁵¹ In some cases, post-LASIK infection may require corneal transplantation.³⁷

CLINICAL MANIFESTATIONS

Signs of sepsis or meningitis caused by *A. xylosoxidans* in the newborn are difficult to differentiate from other causes of bacterial sepsis. However some babies may develop a distinctive rash in association with this infection, in which 1- to 2-cm, sharply demarcated red patches appear, especially in the head and neck region. This rash was noted in 29 of 33 newborns with *A. xylosoxidans* infection reported by Doxiadis and associates in 1960¹⁶ and was seen again in a case reported in 1993.⁷ *A. xylosoxidans* sepsis and meningitis tend to manifest later in life than do infections with the usual vertically acquired pathogens and may have a more insidious onset.⁴⁰ In some cases, cerebrospinal fluid profiles may resemble those usually associated with viral meningitis, with white blood cell counts in the hundreds, and with monocytic predominance.⁵⁶ Neonatal *Achromobacter* sepsis or meningitis has an extremely poor prognosis; one series noted a mortality rate that approached 75%, and 36% of survivors had severe neurologic deficits.²³ The incidence of intracranial hemorrhage also was high.

Three large series of bloodstream infections with *A. xylosoxidans* all revealed a similar story; most cases are nosocomial, most patients have

an underlying malignant disease, many are neutropenic or receiving high-dose steroids, and many have indwelling vascular catheters.^{2,24,58} Polymicrobial bacteremia was not rare in these series. Mortality rates ranged from 15%²⁴ to 48%.⁵⁸ Risk factors for mortality were age older than 65 years at diagnosis, neutropenia, nosocomial acquisition, and polymicrobial bacteremia. An earlier review of reported cases revealed that the case-fatality rate was lowest in patients with catheter-associated bacteremia and highest (65%) in those with pneumonia, meningitis, or endocarditis.¹⁷

An outbreak of urinary tract infection was traced to ultrasound gel used in transrectal ultrasound-guided prostate biopsies.⁴⁵ Urinary tract infections are generally seen in elderly patients with underlying malignancies or urologic abnormalities.⁶⁶ A large NICU outbreak in Brazil involved 22 neonates over the course of 6 months. Features of illness were abdominal distention, thrombocytopenia, and neutropenia. The mortality rate was almost 14%. The source of the outbreak was never determined, and the outbreak ceased only after the NICU was physically moved.⁶⁷

One child developed osteomyelitis caused by *A. xylosoxidans* after stepping on a nail through old sneakers (a clinical situation classically associated with *Pseudomonas* infection)^{28,29}; another developed *Achromobacter* infection as a consequence of a gunshot wound.¹² In the setting of a patient with an artificial heart valve, *A. xylosoxidans* endocarditis has been described.⁴⁶ In another case, endocarditis was associated with an abandoned pacemaker lead.¹ A case series of liver abscesses included three patients from whom *A. xylosoxidans* was isolated, all of whom shared a clinical pattern—history of cholecystectomy, “coral-like” multilobulated appearance on computed tomography, and epithelioid granulomas at the periphery of the abscesses.³ *A. xylosoxidans* infection in older patients usually is not suspected on clinical grounds but rather in the context of a common-source outbreak or because of microbiologic clues. *A. faecalis* infection is less common and usually is part of a polymicrobial process.

A review of *Achromobacter* pulmonary infections found that the majority of cases presented as pneumonia, usually in people with malignancy.⁶³ Two patients suffering from a pertussis-like illness were found to be infected with *A. xylosoxidans* strains carrying the *ptxA* gene.⁴⁷

DIAGNOSIS AND TREATMENT

Generally the diagnosis of *Achromobacter* infections rests on recovery of the organism from clinical samples, although newer methods sometimes have been employed. In one case of culture-negative endophthalmitis, fluid obtained from the anterior chamber was subjected to polymerase chain reaction (PCR) using a 16S rDNA primer set, finding a 214 base pair sequence from *A. xylosoxidans*.⁶⁹ These organisms often are mistaken for pseudomonads, and the clinician should suspect *A. xylosoxidans* when the laboratory reports an organism as a *Pseudomonas* spp. that is resistant to all aminoglycosides.⁵⁵ Key differentiation features include the antibiogram and the morphology of the organism, with its distinctive peritrichous flagella. The organism can be identified in the sputum of CF patients using a PCR for the *bla* (OXA-114-like) gene, which is constitutive in *A. xylosoxidans*.⁶⁸ MALDI-TOF also has been used to identify nonfermenting gram-negative rods in CF sputum with great accuracy, correctly identifying 549/559 strains.¹⁵

Achromobacter spp. typically are resistant to a large number of antibiotics, including ampicillin, aztreonam, aminoglycosides, first- and second-generation cephalosporins, tetracyclines, and rifampin. They variably are resistant to chloramphenicol, fluoroquinolones, macrolides, ureidopenicillins, and β -lactamase combination drugs.⁶ *Achromobacter* spp. have been shown to produce β -lactamases, some of which are chromosomal, constitutive, and inducible¹⁴ and some of which are on plasmids.³⁶ Some isolates overproduce β -lactamase,¹⁴ which stoichiometrically can render β -lactamase inhibitors useless. In addition, their porins are small, thus rendering antibiotic entry difficult. More recently, a multidrug efflux pump of the RND-type has been described.⁴ Although there is no antibiotic to which all isolates have been shown to be sensitive,⁴⁶ most are sensitive in vitro to trimethoprim-sulfamethoxazole, piperacillin-tazobactam, imipenem, ceftazidime, and cefoperazone.

Carbapenem-resistant strains also have been discovered. These strains produced VIM-2, OXA-30, and a chromosomal AmpC β -lactamase.⁶⁰ One isolate harbored both a chromosomal and a plasmid-mediated carbapenemase.⁹ Two case reports describe treatment failures of ceftazidime⁴¹ and piperacillin¹⁴ in clinical isolates that were sensitive at the time of isolation but developed resistance during the course of therapy. In one case of a 14-year-old girl with *A. xylosoxidans* meningitis secondary to a baclofen pump infection, standard treatment with 30-minute infusions of meropenem every 8 hours led to apparent success but with recurrence despite removal of the pump; treatment was successful when a 4-hour infusion was substituted, maintaining the serum level above the minimum inhibitory concentration (MIC) of the organism for at least 75% of the dosing interval.⁴³

Because resistance patterns vary across isolates, the combination of a third-generation cephalosporin, piperacillin (or piperacillin-tazobactam), or meropenem with trimethoprim-sulfamethoxazole is reasonable empirical therapy for suspected *Achromobacter* infection, pending susceptibility results. In general, in vitro susceptibilities seem to correlate well with in vivo results,³⁵ but the risk for inducible resistance to β -lactam antibiotics should be acknowledged. One report described synergy in microbial killing with an aminoglycoside, even though the isolate was resistant to the same aminoglycoside when it was tested alone.¹⁰ This phenomenon was confirmed by two-disk Kirby-Bauer approximation methods using 11 clinical blood culture isolates; all were resistant to gentamicin, but 10 of 11 were inhibited synergistically when gentamicin was added to ticarcillin-clavulanate, and nine of 11 displayed synergy when gentamicin was added to piperacillin or ceftazidime.¹⁷

Removal of infected catheters may speed recovery, although some patients have been treated successfully through indwelling lines.¹⁰ Because of a high recurrence rate, experts in the care of patients with renal failure treated with continuous ambulatory peritoneal dialysis recommend removal of peritoneal catheters in patients who develop peritonitis with *A. xylosoxidans*.²¹

Eikenella corrodens

Jeffrey M. Bender • Randall G. Fisher

Eikenella corrodens is a facultatively anaerobic, fastidious gram-negative rod that is part of the normal flora of the mouth and the gastrointestinal and genitourinary tracts. Long regarded as a commensal, its pathogenicity no longer is in doubt. It frequently is a pathogen of periodontitis in both adults and children and is a common isolate from wounds that have been contaminated by oral secretions. It also has been recovered from pleuropulmonary infections, central nervous system infections, orbital cellulitis, peritonsillar abscesses, abdominal infections, osteomyelitis, and bloodstream infections, including endocarditis.

BACTERIOLOGY

In 1948, Hendriksen described the organism and called it the “corroding bacillus” because it pitted the agar.²⁰ It was characterized more fully in 1958 by Eiken, who named it *Bacteroides corrodens*.¹² In 1972, Jackson and Goodman separated two species of corroding bacteria; the strict anaerobe kept the name *B. corrodens* (now called *B. ureolyticus*), and the facultative anaerobe was classified as *Eikenella*.²¹ It is a small, straight, nonmotile gram-negative rod that occasionally is coccobacillary. It is oxidase positive and catalase negative. Most strains are positive for lysine and ornithine decarboxylase. The organism is nonfermentative, reduces nitrate to nitrite, and is negative for urease and indole. *E.*

corrodens cell surface components vary from isolate to isolate; these differences probably relate to virulence.⁶

E. corrodens will grow either aerobically or anaerobically, but its growth is not rapid. Growth can be enhanced by 3% to 10% carbon dioxide. It grows on blood or chocolate agar but poorly or not at all on MacConkey agar. Selective medium, which contains clindamycin, may increase the yield. Colonies are small and grayish. They look slightly yellow when they are old. Although *E. corrodens* is nonhemolytic, a faint green appearance may be seen on blood agar. Approximately 50% will produce the characteristic pitting. They release an odor that resembles that of bleach or hypochlorite.²¹

E. corrodens is a member of the so-called HACEK family of organisms, which have the following in common: slow growth, a requirement for carbon dioxide, and a predilection for infecting heart valves. The other members of the family are *Aggregatibacter*³⁵ (formerly *Haemophilus*) *aphrophilus*, *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetem-comitans*, *Cardiobacterium hominis*, and *Kingella kingae*.

EPIDEMIOLOGY

Infection with *E. corrodens* occurs when mucosal or skin barriers are disrupted and the organism gains access to deeper tissues. Puncture of the skin with forks³⁷ or toothpicks⁴³ may result in deep-seated infections.

osteomyelitis

bloodstream infections

endocarditis

One case of vertebral osteomyelitis that occurred after a woman accidentally inoculated the organism into the paravertebral space by penetration of a fish bone through the posterior pharynx has been reported.³² In a similar case, a fish bone stuck in the throat for 2 months eventually led to a spinal epidural abscess.²⁵ Infection commonly occurs after clenched-fist injury as a result of fistfighting.¹⁶ Hand infections in children are more likely to be secondary to digital biting or sucking.¹⁸ Intravenous drug abusers are at risk for injection site and soft tissue abscesses,¹⁷ bacteremia, and endocarditis.^{10,36} Elderly persons and patients with advanced carcinomas are the other high-risk groups. However children are at particularly high risk for serious *E. corrodens* infections.⁴² Thyroid abscesses^{7,51} and purulent thyroiditis⁴¹ all have been reported in children. In one review, more than 20% of *E. corrodens* pleuropulmonary infections occurred in children younger than 14 years.²⁷ A separate review demonstrated more than 50% of abdominal *E. corrodens* infections were reported in patients younger than 25 years.⁹ *E. corrodens* orbital cellulitis,¹⁹ empyema,⁴⁸ peritonsillar abscess,²⁸ paronychia,¹ and osteomyelitis^{39,45} have been observed in children. A review of 54 cases of *E. corrodens* infection in children and adolescents revealed that 41% of pediatric infections occurred in the head and neck. The most common single site was the thyroid gland.³⁷

PATHOPHYSIOLOGY

E. corrodens infections often are polymicrobial and may include other anaerobes or gram-negative rods.⁴⁹ However *E. corrodens* is accompanied most frequently by recovery of α -hemolytic streptococci. In most reports, the streptococci were not speciated further, but Jacobs and associates made a case for the *Streptococcus anginosus* group because of similarities between the two organisms (i.e., both are found in the mouth and gastrointestinal tract, both produce local suppurative infection, and both thrive in carbon dioxide-rich, oxygen-poor environments).²³ Brooks and colleagues also reported synergy of the two organisms in a rabbit model of skin infection.⁴ In vitro studies of *E. corrodens* co-cultivated with members of the *S. anginosus* group showed that a significant degree of coaggregation occurs. In addition, exponential growth of *Streptococcus constellatus* and *Streptococcus intermedius* occurs 6 hours into incubation when these species are grown in the presence of *E. corrodens*; in its absence, exponential growth does not occur until 25 hours after inoculation.⁵³

The possible role of *E. corrodens* in periodontitis has not been delineated precisely. However, soluble products of *E. corrodens* induce gene expression and protein production of vascular endothelial growth factor and cause phosphorylation of mitogen-activated protein kinase in vitro, a process that leads to increased production of interleukin-8 and adhesion molecules.⁵⁴ This cascade of inflammatory responses could promote chronic periodontitis.

E. corrodens has a propensity toward formation of an abscess in any location, whether alone or in concert with other organisms. Such formation is a hallmark of central nervous system infection.³ Of intraabdominal infections reported by Danziger and associates, 15 of 19 patients had abscesses.⁹ In two cases of orbital cellulitis reported by Hemady and coworkers, both patients had subperiosteal abscesses.¹⁹ Deep or superficial skin abscesses reported in drug addicts¹⁷ or in clenched-fist injury from fistfighting¹⁶ often recur, even after presumed adequate drainage.⁴⁰

CLINICAL MANIFESTATIONS

Infections with *E. corrodens* are indolent. The time from inoculation to onset of symptoms generally is 1 week or longer.⁴ Many cases show initial improvement with treatment but relapse days later, even with appropriate therapy.^{18,28,38,42} The head and neck are the most common sites of infection at all ages.³⁷

Infection of periodontal sites may be associated with rapid progression and bone resorption thought to be secondary to surface-associated materials of *E. corrodens* and other organisms of periodontitis.³³ Craniofacial and neck infections tend to have prolonged morbidity; many require repeated drainage procedures and long courses of antimicrobial agents.⁴² Central nervous system infections often are preceded by sinus

infections but also have been seen in children with congenital heart disease.^{2,50}

Pleuropulmonary infections are marked by fever, cough, and chest pain. Necrotizing pneumonia with multiple abscesses sometimes is seen. Effusions or empyema are noted in 30%, and cavitation is seen in 8%. Children with a predisposition toward aspiration may be at higher risk.²⁷ In one case, a bedridden 16-year-old girl developed a bronchopleural-cutaneous fistula complicating necrotizing pneumonia with empyema.⁵²

Endocarditis is associated with large, friable vegetations and frequent emboli and often requires valve replacement.¹³ Intravenous drug use has been implicated in approximately half of reported cases.

Abdominal *E. corrodens* infections are seen most commonly as complications of ruptured appendicitis but also have been associated with abdominal trauma and surgery. The clinical course is protracted.⁹

Chorioamnionitis leading to premature delivery has been documented.^{14,24,26,29,47} In one case, the infection precipitated the birth of twins at 23 weeks' gestation and led to the demise of one twin.²⁹

Soft tissue infections tend to be severe. Many require wide debridement and skin grafting. Infection of underlying joints, tendons, or bones is not infrequent and can be necrotizing and even lead to amputation.⁴⁰

DIAGNOSIS

Definitive diagnosis rests on recovery of *E. corrodens* in culture, which can be a difficult task because of the organism's slow growth. *Eikenella* tends to be overgrown by hardier species when it is part of a polymicrobial process and may be missed, especially if the isolate does not pit the agar. All the HACEK organisms can pit agar, although not with the regularity of *E. corrodens*.⁵

Many bacteriology laboratories have difficulty identifying and separating catalase-negative, oxidase-positive, gram-negative rods. Not surprisingly, one report noted that of 100 isolates of *E. corrodens* identified by the National Collection of Type Cultures, only 21 were sent in as probable *E. corrodens*.⁵ Organisms that *E. corrodens* may be mistaken for include the other HACEK organisms, *Aggregatibacter* (formerly *Haemophilus*) *paraphrophilus*, *Moraxella atlantae*, and *Actinobacillus ureae*. Novel identification techniques such as matrix-assisted desorption/ionization-time of flight mass spectrometry (MALDI-TOF)⁸ and 16S sequencing have significantly improved the ability of the clinical lab to identify these organisms.¹¹

TREATMENT

E. corrodens has a very unusual antimicrobial susceptibility pattern: although most isolates are sensitive to penicillin and ampicillin, they are resistant to semisynthetic penicillins, such as methicillin and nafcillin.⁴⁶ Additionally these organisms uniformly are resistant to clindamycin and metronidazole, drugs commonly used to treat anaerobic infections.²² They also variably are resistant to aminoglycosides.

Most isolates are susceptible to piperacillin, second- and third-generation cephalosporins, carbapenems, second- and third-generation fluoroquinolones, and tetracycline. In one report, all of 31 *Eikenella* isolates derived from normal oral flora were susceptible to azithromycin in vitro, though resistant to other macrolides.³⁴ Although penicillin often is cited as the drug of choice, some strains produce β -lactamases. One report associated the β -lactamase with a transposon³¹ and another with a plasmid⁴⁴; one report found a chromosomal enzyme that was not inducible.³⁰ In addition, there are reports of intermediate resistance to penicillin, even in isolates that do not produce a β -lactamase.¹⁵

Incision and drainage of abscesses and debridement of necrotic tissue are essential to recovery from these infections. Therapy should be prolonged after patients apparently have recovered because early cessation of antibiotic therapy tends to be associated with relapse. If patients continue to have fever or other signs of infection days after appropriate therapy has been started, obtaining more images of the infected area may be prudent to detect early reaccumulation of purulence.

Acknowledgments

We thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

***Elizabethkingia* and *Chryseobacterium* Species**

Jeffrey M. Bender • Randall G. Fisher

Members of the genus *Chryseobacterium* (formerly *Flavobacterium*) seldom are associated with human infection. Most disease occurs after exposure to a contaminated environmental source. In 1944, Shulmann and Johnson reported a case of meningitis caused by a previously unidentified, gram-negative bacillus isolated from a 9-day-old premature infant.⁵⁴ The term *Flavobacterium meningosepticum* was proposed for this organism by King in 1959, based on her studies of bacterial isolates associated primarily with neonatal meningitis and septicemia.³⁰ Although neonatal meningitis is the most common manifestation of human disease caused by this genus, sepsis, endocarditis, pneumonia, septic arthritis with penetrating trauma or prosthesis, and skin infection occur in individuals beyond the newborn period.

BACTERIOLOGY

The taxonomy of these organisms is confusing because of frequent changes. All but one of the clinically relevant species of the original genus *Flavobacterium* were reclassified to the genus *Chryseobacterium* in 1994.⁶³ Phylogenetic analysis based on 16S rRNA sequencing demonstrated that the organisms formerly classified as *Chryseobacterium meningosepticum* and *Chryseobacterium miricola* represent a separate lineage. Researchers proposed that these two organisms be moved to a new genus, named *Elizabethkingia* after the microbiologist who first described them.²⁹ The former *Flavobacterium odoratum*, rarely responsible for human disease, has been divided into two species (*odoratus* and *odoratimimus*) reclassified as members of the genus *Myroides*.⁶² *Chryseobacterium indologenes* is the species isolated most frequently from human specimens, but it usually is not associated with significant disease.²⁸ Therefore this chapter focuses mainly on *Elizabethkingia meningosepticum*, which can cause severe infections, especially in newborns. These organisms are long, thin, catalase-positive, gram-negative rods with slightly swollen ends; they are nonmotile, oxidase-positive, weakly fermentative, and proteolytic and grow on solid agar as 1- to 2-mm, convex, glistening colonies of buttery consistency.³⁰ Yellow pigmentation is seen occasionally. Colonies do not demonstrate hemolysis on blood agar but may produce a lavender-green color in the surrounding media as a result of extensive proteolytic enzyme activity. *Elizabethkingia* is unable to grow on *Salmonella-Shigella* agar or Simmons citrate and lacks motility. These characteristics distinguish *Elizabethkingia* from *Pseudomonas*, with which it often is confused.¹⁴ Similarly, the use of glucose in an open tube of oxidation-fermentation media distinguishes *Elizabethkingia* from *Achromobacter faecalis*.¹⁴ The clinically relevant species *E. meningosepticum* (also referred to interchangeably in the current literature by its old name *Chryseobacterium meningosepticum* and in the older literature as *Flavobacterium meningosepticum*) and *Flavobacterium IIB* (renamed *Flavobacterium balustinum*) are differentiated by the former's consistent liquefaction of gelatin and early use of

mannitol and maltose and the latter's lack of these abilities.³⁰ *Myroides odoratus* and *Myroides odoratimimus* (*F. odoratum*), which have been identified most commonly as saprophytes in skin wounds, characteristically are nonsaccharolytic and produce a fruity odor when they are grown on standard media.²⁵

EPIDEMIOLOGY

Elizabethkingia spp. and *Chryseobacterium* are distributed widely as saprophytes in fresh and salt water, as well as in the soil. *E. meningosepticum* has been identified as a pathogen in birds.⁶¹ In hospitals, these organisms have been found to be ubiquitous colonizers of the patient's environment and have been isolated from flower vases,⁵⁹ ice machines,⁵⁷ vials of intravenous drugs,⁴⁴ and nebulizers.¹⁵ In addition, tap water,¹⁵ eyewashes,⁴⁸ tube feedings,¹⁵ sink traps,⁸ and hand cultures of hospital personnel¹⁵ have yielded this organism. In some instances, these reservoirs have been implicated in nosocomial outbreaks of patient colonization and invasive disease.

Neonatal infection caused by *E. meningosepticum* has been reported frequently in the literature, often in association with nursery epidemics.^{2,7,50} As with other neonatal pathogens, infants who are premature and small for gestational age seem to be at particular risk for infection. More than 50% of infected infants weigh less than 2500 g. Almost all cases occur within 3 weeks of birth, and more than 50% of these infants manifest illness before they are 7 days old.¹⁴

Nosocomial epidemics have occurred sporadically since the nursery outbreak reported by Brody and colleagues in 1958.^{2,5,7,8} Cabrera and Davis reported such an outbreak in detail in 1960.⁸ During a 3-month period, the bacteria were isolated from a total of 44 infants, of whom 14 had overt infection. Most colonized infants had organisms isolated from the nasopharynx. The only reservoir of infectious bacteria discovered was a faulty sink trap, beneath which cleaning materials for the nursery were stored. Repair of the defective trap and thorough cleansing and repainting of the nursery coincided with termination of the epidemic. In one situation, respiratory tract colonization developed in four premature neonates, but none of them developed disease; routine infection control measures ensured that no further infants were colonized.⁴⁰

Nursery outbreaks of *E. meningosepticum* have been traced to saline used to flush infants' eyes after administration of silver nitrate,⁴⁸ and organisms have been recovered from washbasins, sinks, disinfectants, and suction devices in other epidemics.⁸ Colonization of patients in a surgical intensive care unit was associated with tap water, sinks, ice machines, and washbasins yielding the bacteria.¹⁵ Ribotyping and random amplified polymorphic DNA fingerprinting (RAPD) offer promise for more precise characterization of epidemics.^{12,13} Use of these techniques has also demonstrated that, in some cases, isolates in what appears to be an outbreak may be unrelated. In one case, isolates from the

surrounding environment were also all unrelated to the types found in the patients.⁶⁴

In 2016, Wisconsin and surrounding states experienced an outbreak of *Elizabethkingia anopheles* infections that affected primarily older adults with underlying medical conditions. Centers for Disease Control–reported cases numbered 65 at time of publication, with 20 deaths. The age range was 19 to 104 years. No children were reported at the time. This species has been associated with significant morbidity and mortality.³¹

PATHOPHYSIOLOGY

Elizabethkingia spp. and *Chryseobacterium* spp. generally are of low virulence. Rabbits administered 1-mL intravenous infections of 24-hour-old broth cultures demonstrated no mortality or morbidity; death rates were less than 30% in mice inoculated intracerebrally with “barely turbid” preparations.³⁰

Most cases of invasive human disease are thought to be caused by environmental contamination with high numbers of *E. meningosepticum*, with spread to the compromised newborn or debilitated older patient. Some neonatal infections may be caused by colonization of the infant during passage through the birth canal of a colonized mother.¹³ Intrapartum infection is supported by occurrence of symptoms as early as 10 hours after birth.¹⁴ However, only 0.3% of genital swabs submitted from patients with suspected sexually transmitted infection yielded the organism.⁴⁴ Continuing reports of *E. meningosepticum* as a cause of neonatal infection in developing countries have been speculated to be related to use of contaminated groundwater for bathing of newborn infants and feminine genital hygiene.¹⁴ The propensity for this organism to produce meningitis in the newborn is not understood, but infection may occur in association with heavy nasopharyngeal colonization, leading to subsequent bacteremia and seeding of the meninges.

Cases in older children have been related to insulin-dependent diabetes mellitus,⁹ thalassemia major with splenectomy,⁴⁶ and oncologic disease with indwelling catheters.⁴³ Peritonitis in patients undergoing continuous ambulatory peritoneal dialysis, including a case series of 30 patients, also has been reported.⁴⁷

In older individuals, *E. meningosepticum* and *Chryseobacterium* primarily play the role of opportunists.³⁹ Heavy nosocomial colonization combined with a blunted immune response probably accounts for the immunocompromised patient's poor capacity to handle this otherwise noninvasive bacterium.

CLINICAL MANIFESTATIONS

Neonatal sepsis and meningitis caused by *E. meningosepticum* share signs and symptoms in common with other forms of neonatal bacterial infection. However, the development of meningitis may be insidious, and several days of illness often pass before its presentation^{14,50}; this factor is consistent with the low virulence of *E. meningosepticum* in contrast to other agents of neonatal sepsis. Prognosis is extremely poor, and mortality rates may exceed 60%.³⁴ Fifty percent of survivors develop significant neurologic complications, often in association with hydrocephalus.³⁵

These organisms are uncommon pathogens in adults, and childhood disease occurring beyond the newborn period is extremely rare. Among the 24 initial isolates of *E. meningosepticum* identified by King, organisms were identified in a throat culture from an adult patient and in cerebrospinal fluid (CSF) from an 8-month-old infant.³⁰ Bacteria formerly classified as *Flavobacterium IIB* (now known as *F. balustinum*) were isolated from the blood and CSF of several adult patients without clinical information.²⁶ Since their initial identification in 1959, these agents have been implicated as causes of meningitis,^{39,50} postoperative bacteremia,^{3,45} bacterial endocarditis,⁶⁵ pneumonia,^{58,59} catheter-associated infection, septic arthritis, and skin infection.¹⁸ *E. meningosepticum* is the clinically relevant species most commonly isolated, but *C. balustinum*, *M. odoratus*, and *M. odoratimimus* (*F. odoratum*) and other *Chryseobacterium* spp. have been implicated in human disease. *Elizabethkingia* and *Chryseobacterium* spp. accounted for 0.25% of infections in a large consecutive series of patients with human immunodeficiency virus infection. Risk factors included low CD4 counts and leukopenia.³⁸

E. meningosepticum meningitis beyond the neonatal period typically occurs in immunocompromised patients. Adults with preexisting leukemia,⁵⁰ glomerulonephritis,³⁹ and squamous cell carcinoma²¹ have been described as having meningitis caused by this organism. In a 56-year-old woman, meningitis with *E. meningosepticum* developed after she underwent transsphenoidal hypophysectomy¹⁰; in an 8-month-old male child with preceding severe neurologic damage, meningitis developed with bacteria designated by the Centers for Disease Control and Prevention as *Flavobacterium*-like organisms. In a 6-week-old infant, *E. meningosepticum* bacteremia and meningitis developed in association with a strangulated hernia.¹⁴

Elizabethkingia and *Chryseobacterium* spp. were isolated frequently from tracheal aspirates of patients in intensive care during a 70-month observation period; yet during that time, none of more than 2000 critically ill patients developed pneumonia attributable to these microbes.¹⁵ However, true respiratory tract infection was identified in an intubated pediatric patient and in adults receiving aerosolized medications.^{6,59}

Sporadic cases of bacteremia have been reported in adult patients.^{21,27,33,36} Two reviews of adult bacteremia in Taiwan have been published.^{27,36} The largest of these included 118 patients at a single center over a 7-year period. The incidence of *E. meningosepticum* bacteremia increased from 7.5/100,000 admissions in 1999 to 35.6 per 100,000 in 2006. The vast majority of these infections were nosocomial, and 60% were acquired in intensive care units. Approximately a third of the patients had malignancy, and a fourth suffered from diabetes mellitus. The 14-day mortality rate was 23.4%. The main risk factor for mortality was acquisition of infection in an intensive care unit setting (odds ratio, 4.23). Rapid institution of appropriate antibiotic therapy reduced mortality.²⁷ Infection in immunocompromised patients can occur as a complication of relatively benign invasive procedures or as a localized infection.^{33,55} Endocarditis was documented in intravenous drug abusers and patients undergoing dialysis.^{17,65} Postoperative bacteremia in eight adult patients was linked to contaminated intravenous medications infused during anesthesia.⁴⁴ Contaminated arterial catheters were implicated in an epidemic of *Chryseobacterium* bacteremia.⁵⁷ Four patients, including a 7-year-old boy, became bacteremic in an outbreak associated with contamination at the time of intracardiac surgery.³ This organism also has been associated with bacteremia in pediatric burn patients.⁵³

Chryseobacterium spp. also have been isolated from infected skin lesions manifesting as papules, sheetlike lesions, plaques, and deep panniculitis.¹⁸ One fatal case of necrotizing fasciitis in a patient with diabetes mellitus and chronic heart failure was reported.³² Infection may have been related to wound contamination during repair of an orthopedic injury. A woman with pemphigus vulgaris developed cellulitis and sepsis.⁵⁶

DIAGNOSIS

Rapid identification of infection with these organisms is urgent, not only to ensure providing proper therapy for the patient, but also to hasten initiating appropriate infection control measures to forestall epidemic outbreaks. Identification of *E. meningosepticum* is hindered by characteristically long periods required for oxidation of carbohydrates and weak or delayed indole production. Cultures may be misidentified as species of *Achromobacter* or *Pseudomonas*.¹⁴ Clinical isolation of an unidentified gram-negative rod that is catalase- and oxidase-positive and that shows multiple antibiotic resistance should raise suspicion of *E. meningosepticum* infection. Cultures should be kept for several days for observation for typical carbohydrate reactions, which confirm the diagnosis.^{14,49}

Identification of *Elizabethkingia* and *Chryseobacterium* species have improved with novel microbiology laboratory techniques. Matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF) was used to quickly identify *C. meningosepticum* in an immunocompetent adult significantly reducing the time to identification and appropriate therapy.²³ 16S sequencing has become the routine definitive reference method in difficult to identify organisms such as *Elizabethkingia* and *Chryseobacterium* species.⁵² Pulse-field gel electrophoresis of DNA

was used successfully to identify recurrence of intravenous catheter-associated infection in a 6-year-old boy with non-Hodgkin lymphoma.⁵¹ In 2016, clinical isolates of *E. anopheles* in Wisconsin were initially characterized using MALDI-TOF and subsequently confirmed to be associated with a multistate outbreak through whole-genome sequencing techniques.⁴²

TREATMENT

Unfortunately, treatment of *E. meningosepticum* meningitis represents an especially difficult challenge for the physician. The organism is paradoxically likely to be sensitive to drugs commonly employed against gram-positive organisms (i.e., rifampin, vancomycin, clindamycin, and trimethoprim-sulfamethoxazole) and resistant to those used to treat gram-negative infections (i.e., aminoglycosides, cephalosporins, tetracyclines, and carbapenems). Most *Elizabethkingia* and *Chryseobacterium* spp. produce broad-spectrum metallo- β -lactamases. In *E. meningosepticum*, the enzyme is highly efficient at hydrolyzing carbapenems. Inactivation of cephalosporins displays a remarkable variability that is based on the affinity of the enzyme for the different compounds.⁶³ Delay in establishing a specific identification of the organism has historically led to ineffectual therapy as isolates of *E. meningosepticum* are almost uniformly resistant to common empiric gram-negative meningitis antibiotics such as third-generation cephalosporins or ampicillin and an aminoglycoside. Moreover antimicrobial susceptibilities determined by disk diffusion must be interpreted with caution. Aber and associates found clinical isolates in which specific strains were sensitive to gentamicin and rifampin by disk diffusion but were resistant by agar gel dilution susceptibility testing.¹ Therefore more direct methods of measuring the minimal inhibitory concentration than disk diffusion sensitivity should be used to determine the optimal microbial agents for therapy.

Probably as a consequence of difficulties encountered in providing rapid and effective antibacterial therapy, these organisms frequently persist for prolonged periods in CSF. Average persistence of *E. meningosepticum* in CSF is 19 days,¹⁴ in contrast to the 3.9 days described by McCracken⁴¹ for most cases of gram-negative neonatal bacterial meningitis.

Studies of in vitro susceptibility data forced a reappraisal of the idea that vancomycin is a good first-line choice for the treatment of *Chryseobacterium* infection. In one report, a literature review showed that only 65% of historic isolates were susceptible to vancomycin⁴; in another, a thorough search for a susceptible organism among 58 clinical isolates met with failure.¹⁹ Clinically drugs that have been used alone or in combination with some success have included erythromycin, vancomycin, trimethoprim-sulfamethoxazole, fluoroquinolones (especially levofloxacin), and rifampin.⁶⁰ Some of these agents have the potential disadvantage of poor penetration of CSF. Combined use of many of these drugs renders interpreting therapeutic response difficult. The 3 survivors among the 12 patients reported by George and associates all received vancomycin intravenously, intrathecally, or both, as a part of their regimen.²⁰ Hawley and Gump reported a case of *E. meningosepticum* meningitis in a neonate who responded to systemic vancomycin after unsuccessful treatment with multiple antibiotics, including erythromycin.²²

Intraventricular erythromycin^{16,50} or rifampin^{11,34,35,50} has been used in conjunction with systemic administration of these drugs. In particular, Lee and associates reported no deaths in seven infants with *E. meningosepticum* meningitis who were treated with intraventricular rifampin through an Ommaya reservoir at a dosage of 2 to 5 mg every 24 hours combined with 40 mg/kg per day administered intravenously.³⁵ Intra-

ventricular administration continued until the CSF was sterile. However, colonization of the Ommaya reservoir was a common finding, and formation of a porencephalic cyst occurred in one patient. Chandrika and Adler reported sterilization of ventricles in one afflicted neonate within 48 hours after institution of therapy with intraventricular and intravenous rifampin.¹¹ Erythromycin has been used intraventricularly with limited success at 5 to 10 mg/day.^{16,50} Rios and associates reported the successful addition of intraventricular rifampin to a failing regimen of intravenous and intraventricular erythromycin.⁵⁰ Development of resistance during therapy has been demonstrated with erythromycin and rifampin; persistence of organisms in the CSF despite administration of presumably adequate therapy should alert the physician to test for this possibility.^{16,50} Addition of trimethoprim-sulfamethoxazole may be of benefit with such an occurrence; this agent effected a bacteriologic cure in eight of nine infants with meningitis.³⁷ This agent usually is not recommended in the neonatal period because of possible displacement of bilirubin from albumin-binding sites. Bacterial eradication was achieved in 48 hours in two patients with meningitis who were treated with clindamycin, rifampin, and cefotaxime systemically and rifampin intraventricularly.⁷

As with other types of gram-negative meningitis, antimicrobial therapy should be continued for at least 2 weeks after sterilization of ventricular fluid has been achieved. Time to sterilization is frequently prolonged; most patients therefore require 4 to 6 weeks of antimicrobial therapy. Complications of hydrocephalus and the potential use of intraventricular therapy render the neurosurgeon an essential part of the management team. Historically mortality has been in excess of 70%, no doubt in part because of delays in identifying the organism and the limited antibiotic spectrum available for effective therapy. More recent series of patients, although small, suggest some improvement in this statistic, but the rate of hydrocephalus and neurologic deficits remains high.

Recovery has been the rule in immunocompetent older individuals infected with contaminated materials, often despite treatment with antibiotics to which the organism was insensitive, a finding highlighting the very low virulence of these organisms in immunocompetent adults.³⁹ However, significant mortality and morbidity often occur in immunocompromised individuals with bacteremia or meningitis. Use of chloramphenicol, vancomycin, levofloxacin, erythromycin, or rifampin has achieved some success in these patients, but the choice of antibiotic must be based on a detailed examination of the organism's susceptibility.^{24,53}

The genus *Pseudomonas* is large and complex, containing a significant number of bacterial species, most of which are found in the environment as saprophytes and not associated with human or animal infections. Early attempts at better understanding the taxonomy of this diverse group of organisms led to placement of *Pseudomonas* spp. into five species clusters of genetically related organisms, also known as ribosomal RNA (rRNA) homology groups (designated groups I to V).¹⁵⁸ This genus since has undergone extensive revision using DNA-DNA hybridization, 16S rRNA sequencing, and related techniques, with four of the five homology groups reclassified into different genera (Table 125.1).²¹⁹ The taxon *Pseudomonas* was retained for organisms in rRNA homology group I with *P. aeruginosa* as the type species. Although they can cause infections in otherwise healthy individuals, they are more commonly opportunistic human pathogens causing disease in patients with burn wounds, cystic fibrosis (CF), malignancy, or immunodeficiency, as well as in individuals who are malnourished, are receiving immunosuppressive therapy, or have indwelling devices. The most important species by far relating to human disease is *P. aeruginosa*; however, some other related organisms are less commonly associated with specific clinical syndromes in both children and adults. This chapter will focus on *Pseudomonas*

spp. (classic rRNA group I organisms) and *Burkholderia*, *Ralstonia*, *Cupriavidus*, and *Pandora* spp. (classic rRNA group II and related organisms) of primary clinical significance in pediatric patients.

ETIOLOGY

Pseudomonas spp. and related genera (pseudomonads) are nonfastidious, nonfermentative, obligate aerobic (i.e., metabolize carbohydrates oxidatively and thus require molecular oxygen as the terminal hydrogen/electron acceptor), catalase positive, generally cytochrome oxidase positive and motile, non-spore-forming, gram-negative bacilli. Some species, including *P. aeruginosa*, may grow anaerobically in the presence of nitrates or other nonorganic compounds as terminal hydrogen/electron acceptors. This has clinical relevance for CF, allowing *P. aeruginosa* to grow in the relatively anaerobic atmosphere within the sputum and mucous of such patients.^{1,204,395} Because pseudomonads can metabolize a wide variety of carbon sources, including simple and complex carbohydrates, alcohols, and amino acids, they can survive and multiply in almost any moist environment containing minimal amounts of organic compounds.

Among the *Pseudomonas* species (former rRNA homology group I organisms), a division is made into two groups on the basis of production of fluorescent pigments. The “fluorescent pseudomonads” include six clinically relevant members: *P. aeruginosa*, *P. putida*, *P. fluorescens*, and less commonly encountered species, *P. veronii*, *P. monteilii*, and *P. mosselii*. The nonfluorescent group includes six clinically relevant species: *P. stutzeri* and *P. mendocina* (*stutzeri* group), *P. alcaligenes* and *P. pseudoalcaligenes* (*alcaligenes* group), and *P. luteola* and *P. oryzihabitans* (*yellow-pigmented* group).¹⁶⁵ The fluorescent pseudomonads generally produce the water-soluble yellow-green fluorescent pigment pyoverdine (fluorescein), whereas many clinical isolates of *P. aeruginosa* also produce the water-soluble blue phenazine pigment pyocyanin. These pigments diffuse into and color the medium surrounding the colonies. The pyoverdine and pyocyanin produced by *P. aeruginosa* combine to give the bright-green to blue-green color characteristic of this organism on certain clear laboratory media, particularly Mueller-Hinton agar. Some strains of *P. aeruginosa* may produce other pigments, such as dark red (pyorubin) or brown-black (pyomelanin) pigment.

P. aeruginosa is readily recovered from clinical specimens and usually is recognized easily on laboratory media such as sheep blood agar by its characteristic flat-spreading colonies with a metallic-sheen, an irregular edge, and production of β -hemolysis; however, atypical colony types such as smooth-round, mucoid, or small colony variants may occur, particularly in patients with CF. These atypical colony types are likely due to the impact of previous antibiotic therapy on synthetic biochemical pathways. It is common to recover a mixture of colony types in such patients. On selective and differential MacConkey agar, *P. aeruginosa* produces colorless colonies because lactose is not used as a sole carbohydrate source and there is no change in pH of the medium. When pigment production and typical metallic-sheen colony type are combined with a positive cytochrome oxidase test, *P. aeruginosa* can be identified with high certainty without further testing.⁷² Many laboratories rely on commercial biochemical identification systems for identifying gram-negative rods suspected of being *P. aeruginosa*, particularly those with atypical colony morphology. Most such systems are highly accurate (>90%) for identification of *P. aeruginosa*, but less accurate for identification of other *Pseudomonas* spp. Such systems for identification of *P. aeruginosa* isolates from patients with CF are less accurate, particularly for slow-growing or variant colony types. Some systems may have difficulty separating the three closely related fluorescent pseudomonads,

TABLE 125.1 Taxonomic Changes Associated With *Pseudomonas* spp. and Related Organisms Causing Disease in Humans

RNA Homology Group	Previous Species Designation	Current Species Designation
I		<i>Pseudomonas aeruginosa</i> <i>Pseudomonas fluorescens</i> <i>Pseudomonas putida</i> <i>Pseudomonas monteilii</i> <i>Pseudomonas mosselii</i> <i>Pseudomonas veronii</i> <i>Pseudomonas stutzeri</i> <i>Pseudomonas mendocina</i> <i>Pseudomonas pseudoalcaligenes</i> <i>Pseudomonas alcaligenes</i> <i>Chryseomonas luteola</i> <i>Flavimonas oryzihabitans</i>
II	<i>Pseudomonas cepacia</i> <i>Pseudomonas gladioli</i> <i>Pseudomonas mallei</i> <i>Pseudomonas pickettii</i> <i>Pseudomonas pseudomallei</i>	<i>Burkholderia cepacia</i> <i>Burkholderia gladioli</i> <i>Burkholderia mallei</i> <i>Ralstonia pickettii</i> <i>Burkholderia pseudomallei</i>
III	<i>Pseudomonas acidovorans</i> <i>Pseudomonas testosteroni</i> <i>Pseudomonas delafieldii</i> <i>Hydrogenomonas facilis</i>	<i>Delftia acidovorans</i> <i>Comamonas testosteroni</i> <i>Acidovorax delafieldii</i> <i>Acidovorax facilis</i>
IV	<i>Pseudomonas diminuta</i> <i>Pseudomonas vesicularis</i>	<i>Brevundimonas diminuta</i> <i>Brevundimonas vesicularis</i>
V	<i>Xanthomonas maltophilia</i>	<i>Stenotrophomonas maltophilia</i>

Based on Henry DA, Speert DP. *Pseudomonas*. In: Versalovic J, Carroll KC, Tenover FC, et al., editors. *Manual of Clinical Microbiology*, 10th ed. Washington, DC: ASM Press; 2011.

and thus definitive identification may require additional testing. Although growth is optimal at 35° to 37°C (95°F–98.6°F), *P. aeruginosa* grows at 42°C (107.6°F) and *P. fluorescens* and *P. putida* do not. In addition, most isolates of *P. aeruginosa* reduce nitrogen to gas, whereas the other two fluorescent *Pseudomonas* spp. do not. Additional biochemical characteristics of *P. aeruginosa* include a reaction of alkaline over no change in triple sugar iron agar; production of acid oxidatively from glucose and xylose but not lactose, sucrose, or maltose; and a positive reaction for arginine dihydrolase. In practice, these latter tests are generally not used because they do not clearly differentiate among the fluorescent pseudomonads. Most strains are motile by one or more polar flagella and also display surface pili. Most isolates also carry the genes required to synthesize the extracellular mucopolysaccharide alginate, whose overproduction results in the mucoid colony type; however, such colony types are almost exclusively isolated from the respiratory tract of patients with CF.²⁴⁰

Among the nonfluorescent group *Pseudomonas* spp., *P. luteola* and *P. oryzihabitans* are somewhat unique because they are cytochrome oxidase negative and produce an intracellular yellow, nondiffusible pigment. Most isolates of *P. stutzeri* produce a distinctive dry, wrinkled colony on agar media, and the colonies can adhere tenaciously to the agar. In contrast, *P. mendocina* produces smooth colonies with a brown-yellow pigment. Isolates of *P. alcaligenes* and *P. pseudoalcaligenes* do not produce distinctive colony types and are rarely encountered in clinical specimens. As a group, these organisms are identified with variable accuracy by commercial biochemical identification systems. Depending on the clinical situation, an identification of *Pseudomonas*-like gram-negative rod or *Pseudomonas* spp., not *aeruginosa*, with a request to contact the laboratory for further identification and antimicrobial susceptibility testing may be sufficient. When definitive identification is required, nucleic acid–based methods for identification of culture isolates of *Pseudomonas* spp. have proved useful. These methods include sequencing of the genes coding for 16S rRNA or the use of specific nucleic acid probes or polymerase chain reaction (PCR) assays, such as assays targeting the exotoxin A or other *P. aeruginosa*-specific gene sequences. Peptide nucleic acid fluorescence in situ hybridization has also been shown to be sensitive and specific for identification of *P. aeruginosa*, including identification in positive blood culture bottles. As will be mentioned later, newer techniques such as matrix-assisted laser desorption/ionization–time of flight mass (MALDI-TOF) spectrometry have been shown to be reliable and accurate in providing identifications of these organisms.

The former rRNA homology group 2 and related organisms currently comprise a diverse group of bacteria in the genera *Burkholderia*, *Ralstonia*, *Cupriavidus*, and *Pandoraea*. Like the *Pseudomonas* spp., they are found in a wide variety of environmental habitats as saprophytes, plant pathogens, and opportunistic animal and human pathogens and are nutritionally versatile. The more well-studied organisms in the group belong to the genus *Burkholderia*, which now contains more than 60 species. Members of this genus can be divided into two major groups: the *B. cepacia* complex and non-*B. cepacia* complex organisms. There are currently 18 named *B. cepacia* complex organisms with all but one having been recovered from human specimens.²²⁰ The most important species in the complex are *B. multivorans* and *B. cenocepacia* because of their role as colonizers and opportunistic pathogens in patients with CF; they compromise approximately 80% of *B. cepacia* complex infections in the United States.²²⁰ Of the non-*B. cepacia* complex *Burkholderia* spp., those of human clinical significance include *B. gladioli* and *B. pseudomallei*. *B. gladioli* is an important agent of respiratory tract colonization and infection in patients with CF and chronic granulomatous disease.³²⁹ *B. pseudomallei* causes melioidosis and has also been recovered from the respiratory tract of patients with CF. *Burkholderia mallei* is an important animal pathogen causing glanders in horses.

The genera *Ralstonia*, *Cupriavidus*, and *Pandoraea* all contain species of clinical significance, but they are recovered in culture at lower rates than *Burkholderia* spp. The genus *Ralstonia* includes at least five species, with the following species known to cause human infections: *R. pickettii*, *R. insidiosa*, and *R. mannitolilytica*.^{75,77} *R. mannitolilytica* has been reported as causing meningitis and nosocomial outbreaks.^{93,176} The genus *Cupriavidus* contains at least 11 species, including *C. gilardii*, *C. respiraculi*,

C. taiwanensis, and *C. pauculus*, the latter of which have been recovered from patients with CF.³⁷² The genus *Pandoraea* contains at least five named species (i.e., *P. apista*, *P. pulmonicola*, *P. pnomenusa*, *P. sputorum*, and *P. norimbergensis*) and several unnamed species.⁷⁶ *P. apista*, *P. pnomenusa*, and *P. sputorum* have been recovered from patients with CF.¹²² As a group, these organisms are of low virulence and infection in healthy individuals is uncommon. They have been associated with catheter-related bloodstream infections and other health care–associated infections in immunocompromised patients and with colonization and infection in those with CF.

As a group, these organisms grow well but slowly on most standard laboratory media such as sheep blood, chocolate, and MacConkey agars and appear as small, smooth, raised colonies. They may appear as colorless colonies or, with prolonged incubation, pink to dark-red colonies because of the slow usage of lactose, as is usually the case with *B. cepacia* complex organisms. They are all cytochrome oxidase weak or strong positive, gram-negative, motile rods, except for *B. gladioli* and *Pandoraea* spp., which are oxidase variable. A majority of *B. cepacia* complex isolates are lysine decarboxylase positive, a helpful feature in identification of this group. Isolation of *B. cepacia* complex organisms from clinical specimens with mixed bacterial flora, particularly the respiratory tract of patients with CF, is enhanced by using selective and differential media with the ability to inhibit the growth of *P. aeruginosa* and other gram-negative rods. In addition, recovery may be improved if culture plates are incubated at least 3 days at 35°C to 37°C (95°F–98.6°F). Several selective agar media are commercially available, including oxidative-fermentative base–polymyxin B–bacitracin–lactose (OFPBL),³⁸⁶ “P” *cepacia* (PC), and *B. cepacia*–selective (BCSA) agars.^{159,397} These media take advantage of the fact that *Burkholderia* spp. and some related organisms are generally resistant in vitro to the polymyxin antibiotics, whereas *P. aeruginosa* and most commonly isolated enteric bacteria are susceptible (*Serratia* spp. are a notable exception) and therefore inhibited on such media. Several studies have shown differences in the ability of these media to recover *B. cepacia* complex organisms or to inhibit the growth of other bacterial flora, with BCSA being equivalent or superior to the other media for this purpose.^{159,397} Some of these media are also useful for the recovery of *B. gladioli* from patients with CF.

B. pseudomallei grows on agar media commonly used for isolation of gram-negative bacteria. The colonies develop slowly (over a week) and have a characteristic “daisy-head” appearance. α -Hemolysis is noted on sheep blood agar. Ashdown selective medium, which contains crystal violet and gentamicin, can increase the recovery rate of *B. pseudomallei* from clinical specimens containing mixed bacterial flora, including throat, rectal, and sputum specimens.¹⁴ *B. pseudomallei* produces a dry, wrinkled, violet-purple colony with a pungent, earthy odor on Ashdown medium.²²⁰ Other selective media, including a recently described *B. pseudomallei*–selective agar (BPSA) and selective media for *B. cepacia* (BCSA, PC, and OFPBL), have been evaluated against Ashdown medium for the recovery of *B. pseudomallei*.^{144,278} Ashdown medium remains the recommended medium for recovery of *B. pseudomallei* in endemic areas, but commercially available selective agars for *B. cepacia*, particularly PC agar, are acceptable media in nonendemic areas. Selective enrichment broths also have been developed for the recovery of *B. pseudomallei* from superficial sites. Such broths have been shown to improve the recovery of the organism when used in addition to direct plating onto Ashdown medium. Because of the potential of *B. pseudomallei* as an agent of bioterrorism via inhalation, isolation of the organism from patients with no travel history to endemic sites should immediately be reported to public health.

Accurate identification of the rRNA group II and related organisms may be difficult using either traditional biochemical or commercially available biochemical test systems.^{137,198,297,299} Few of these species are found in the databases of such systems, and none of these systems is able to clearly differentiate among the various species in the *B. cepacia* complex. As with *P. aeruginosa*, molecular methods including amplification of the 16S rRNA gene followed by sequencing have been most widely used for this purpose; however, such methods may not always discriminate among closely related pseudomonads. Special emphasis should be given to accurate identification of such organisms when recovered from patients with CF because of the clinical significance

and patient management implication of a *B. cepacia* complex or related organisms in such patients. An initial, probably biochemical, identification of *B. cepacia* complex for a patient with CF should be confirmed with a molecular method capable of determining the exact species identification. To this end, the Cystic Fibrosis Foundation established a *B. cepacia* reference laboratory at the University of Michigan for phenotypic characterization and genotypic species identification for suspected *B. cepacia* complex and related organisms.

MALDI-TOF spectrometry is quickly supplanting phenotypic methods and is becoming the standard bacterial identification method for many laboratories. It is capable of identifying a wide variety of bacteria, including the difficult to identify organisms recovered from the respiratory tract of patients with CF.^{5,98,118,231} MALDI-TOF allows for the analysis of biomolecules such as nucleic acids, proteins, and sugars, as well as other large organic molecules that may be fragile and fragment when ionized by more conventional ionization methods. It has been shown to provide accuracy to the genus and, in most cases, species or subspecies level, which is very useful for organisms in the rRNA groups II through V.

EPIDEMIOLOGY

P. aeruginosa is a ubiquitous environmental organism found in soil, water, and on vegetation, including the surface of many raw fruits and vegetables. Its minimal nutritional requirements and ability to grow in a wide variety of physical environments enhance the organism's ability to survive in numerous ecologic niches. *P. aeruginosa* may be found as colonizing flora in a small percentage of healthy humans.¹⁵⁴ Sites of colonization include moist body sites and mucosal surfaces such as throat, nasal mucosa, axillae, and perineum. Carriage rates in the gastrointestinal tract have been reported as high as 24% based on selective culture of stool. The gastrointestinal tract may be the site of transient colonization after ingestion of food or liquids containing *P. aeruginosa*. Despite the ability to colonize skin and mucosal surfaces, it rarely results in persistent colonization. The respiratory tract is a common site of colonization of patients who have been hospitalized for extended periods, have foreign bodies in place (i.e., endotracheal tubes or tracheostomies), have poor mucociliary clearance, or have received broad-spectrum antibiotics or chemotherapy.

P. aeruginosa is best classified as an opportunistic pathogen whose pathogenic potential is manifest in situations in which the host's immune defenses are diminished or lacking. Such situations include children with poor mucociliary clearance (CF), neutropenia (secondary to cancer chemotherapy), or damaged skin barrier (burn wound). The organism generally does not invade intact skin or mucous membranes.

P. aeruginosa frequently enters the hospital environment on the clothes and shoes of patients, visitors, or hospital personnel and also from the same individuals with skin, gastrointestinal tract, or respiratory tract colonization. It may also enter the hospital on plants or flowers. As a result, the organism may be found growing in any moist hospital environment, including hospital kitchens and laundries, mops, shower heads, whirlpools, antiseptic solutions, eye drops, distilled water sources, irrigation fluid, dialysis fluid, and equipment used for dialysis and respiratory care or inhalation therapy. It tolerates elevated temperatures and can grow in distilled water sources containing only inorganic compounds. *P. aeruginosa* commonly is found on the surface of many types of plants and flowers, raw fruits, and vegetables. Consumption of these foods by profoundly immunosuppressed children can result in colonization of the gastrointestinal tract and potentially can lead to invasive disease. In hospitalized patients, the likelihood of colonization increases with duration of hospitalization. Transmission of *P. aeruginosa* from patient to patient or from hospital personnel to patient often is assumed but rarely documented.^{11,12,103,388} Although clear evidence exists of patient-to-patient transmission of "epidemic strains" of *P. aeruginosa* among the CF population, the relative importance of this mode of acquisition as opposed to acquisition from environmental sources is unclear.^{4,147,218} Environmental sources of *P. aeruginosa* outside the hospital that may result in colonization with subsequent infection include swimming pools, water slides, hot tubs, contact lens solutions, cosmetics, illicit injectable drugs, and the inner soles of sneakers.

Various typing systems have been used to characterize strains of *P. aeruginosa* for epidemiologic purposes; these can be classified as either phenotypic or genotypic typing methods. Historically the phenotypic method of serologic typing based on the O-polysaccharide component of lipopolysaccharide was used most often, but some strains of *P. aeruginosa* lack the O-polysaccharide. Other phenotypic typing methods include phage and pyocin typing. These methods have limited ability to differentiate strains, particularly from chronic infections, because of the variability of gene expression in this organism. Phenotypic methods have been replaced by genotypic methods, including restriction fragment length polymorphism (RFLP) analysis, pulsed-field gel electrophoresis (PFGE), random amplified polymorphic DNA (RAPD) analysis, multilocus sequence typing (MLST), and others.^{81,345} Each of these methods has certain advantages and disadvantages in terms of cost, complexity, and discriminatory power. They have proved helpful in demonstrating, for example, that patients with CF were usually infected with unique strains of *P. aeruginosa* that they harbored for extended periods rather than being replaced by other strains.

The environmental distribution of the other *Pseudomonas* spp. is similar to that of *P. aeruginosa*, and hospitalized as well as nonhospitalized individuals can become transiently colonized. Infection may infrequently occur, particularly in individuals who are immunocompromised. *P. fluorescens* can be isolated from the skin.³²⁷ *P. fluorescens* has been responsible for bloodstream infections, with most cases being iatrogenic, attributable to transfusion with contaminated blood products or infusion equipment.^{322,327} In addition, contamination of blood with *P. fluorescens* during the blood culture collection process has been responsible for outbreaks of pseudobacteremia.^{193,336} *Pseudomonas pseudoalcaligenes* has one of the more unusual environmental habitats—industrial metalworking fluid consisting of a mixture of water and petroleum products. Although metalworkers with long-term exposure to aerosols containing high concentrations ($>10^5$ organisms/mL) of *P. pseudoalcaligenes* develop high antibody titers to the organism, they do not have clinical evidence of acute or chronic respiratory or systemic disease.²³³ Limited data exist on typing systems for *Pseudomonas* spp. other than *P. aeruginosa*.

B. cepacia complex and related organisms are ubiquitous in nature and can be found in water, soil, decaying organic matter, and as plant pathogens.^{171,211,373} Unlike *P. aeruginosa*, *B. cepacia* complex organisms are infrequently encountered in the hospital environment or nonhospital sites such as swimming pools, sinks, and showers. As a group, these organisms are intrinsically resistant to disinfectants and a wide range of antimicrobial agents, including the aminoglycosides and carboxypenicillins (e.g., ticarcillin and carbenicillin). Moreover resistance can be acquired to quinolones, extended-spectrum penicillin/ β -lactamase inhibitor compounds, third- and fourth-generation cephalosporins, and carbapenem antibiotics. *B. cepacia* can survive for extended periods in moist environments, even in the presence of disinfectants, including povidone-iodine.⁹ These organisms have been identified as agents of sporadic nosocomial outbreaks of infection in medical intensive care units. When such outbreaks occur, they have been traced to contaminated instruments and solutions, such as in automated peritoneal dialysis machines, blood gas analyzers, mouthwashes, ultrasound gels, medications, and skin antiseptics, including povidone-iodine and chlorhexidine.^{29,30,157,341} In patients with CF, colonization of the respiratory tract, sometimes associated with lower respiratory tract and disseminated infection, is of major clinical significance because of the association of this organism group with increased morbidity and mortality.^{147,172,220} Although acquisition of *B. cepacia* complex organisms from the environment is the more common mode of transmission, as evidenced by the fact that the majority of infected patients harbor genetically distinct strains, epidemiologic investigations have clearly demonstrated "epidemic strains" and interpatient transmission in the CF population.^{20,34} Most data suggest that, once colonized with a specific strain, replacement of that strain with another strain occurs infrequently.³¹ *B. cepacia* complex organisms also have become more important as a cause of infection and complications in patients with chronic granulomatous disease³⁴⁶ and sickle-cell hemoglobinopathies.³²

B. gladioli, like *B. cepacia* complex organisms, is a plant pathogen found in water and soil. It is associated with infections in immunocompromised patients, including patients with chronic granulomatous

disease and in patients with CF. In fact, it is recovered more frequently from patients with CF than most *B. cepacia* complex species other than *B. cenocepacia* and *B. multivorans*. *B. pseudomallei*, the causative agent of melioidosis, and the closely related species *B. thailandensis*, are found in soil and surface water in the tropical and subtropical areas of Southeast Asia and northern Australia, including rice paddy surface waters in rice-growing areas of Thailand, Cambodia, Vietnam, and Laos.^{63,87,342} *Ralstonia*, *Cupriavidus*, and *Pandoraea* spp. are also found in soil and water sources, but their epidemiology has not been well studied. Unlike some *B. cepacia* complex species, person-to-person transmission of other *Burkholderia* spp. or *Ralstonia*, *Cupriavidus*, and *Pandoraea* spp. has been rarely reported. The first documented spread of *P. pulmonicola* was reported in a CF center in France; the index patient was chronically colonized, and the infection spread to five other individuals.⁹⁵

Genotypic typing systems have been applied to epidemiologic investigations of *B. cepacia* complex organisms, other *Burkholderia* spp., and species of other genera in this group.²²⁰

PATHOGENESIS

Among the *Pseudomonas* spp., the pathogenesis of infections with *P. aeruginosa* has been well studied. Pathogenesis is multifactorial,^{26,224} and the outcome of *P. aeruginosa*–host encounters depends on a variety of organism-specific and host factors. To establish lung infection, for example, *P. aeruginosa* must contend with the mucociliary clearance mechanism and innate immunity, including antibacterial peptides such as lactoferrin, and the action of phagocytic cells.³⁰⁹ The large genome of the organism provides it with the metabolic flexibility to adapt to various host environments. A large number of varied and redundant virulence factors include cell-associated (bound to the bacterial cell surface) and extracellular proteins and other macromolecules, which are either injected directly into the host cell cytoplasm or secreted into the general extracellular environment.³⁷⁴ These factors, along with intrinsic and acquired resistance to antimicrobial agents, allow the organism to colonize, resist host defense mechanisms, produce local tissue damage, and, in some situations, invade and result in disseminated infection despite the host immune response.^{374,390}

Expression of virulence factors is under tight regulatory control and depends on the body site and type of infection. Different factors may be expressed in acute versus chronic infections. Two major types of regulatory systems promote organism survival and proliferation. The first system type involves one- or two-component transcriptional regulatory secretion of exoproteins. One-step systems promote direct delivery of preformed exoproteins, whereas two-step systems synthesize exoproteins as precursor molecules requiring cleavage before exporting outside the cell.¹⁴⁶ In either case, exoproteins are delivered across the inner and outer cell membranes and peptidoglycan cell wall layer to the periplasmic space. The second regulatory system type involves quorum-sensing regulatory systems that help coordinate gene expression throughout the bacterial population to aid the organism in adapting to environmental conditions. Quorum-sensing systems involve cell-to-cell signaling by production of small diffusible molecules known as auto-inducers. Quorum sensing plays an important role in promoting the formation of biofilms on mucosal surfaces and internalized medical devices. Such biofilms are important for survival of the organism and contribute to persistent and chronic infections. Interestingly, macrolide antibiotics, which do not inhibit growth of *P. aeruginosa* in vitro, may inhibit quorum sensing and biofilm formation.^{363,374}

P. aeruginosa displays virtually all known classes of microbial virulence factors. Cell-associated virulence factors include flagella, pili, and endotoxin (lipopolysaccharide). Flagella and pili play an important role in establishment of initial infection because of their functions of providing motility and binding to specific epithelial cell surface receptors. *P. aeruginosa* has one or more polar flagella that allow for motility and appear to be important in initial stages of lung colonization. The flagella themselves do not appear to enhance binding to epithelial cells, but they do bind to respiratory mucin produced in response to infection and may contribute to other cell-binding mechanisms. Decreased clearance of mucin in the lung of some individuals may contribute to establishment of infection. Flagellar proteins contribute to excess

activation of proinflammatory cytokines. Once infection is established in the lung, flagella are generally no longer produced, and they are usually not found in organisms associated with biofilms. Strains of *P. aeruginosa* that lack flagella are less capable of dissemination from wounds and less likely to cause bacteremia and pneumonia in animal models.^{13,106,120} Pili, like flagella, are also found at the poles of the *P. aeruginosa* rod. They promote adherence to mucosal epithelial cells by binding to specific cell-surface glycolipids.³⁷⁸ They also mediate twitching motility, which appears to be important in biofilm formation, as demonstrated by in vitro models.

Other cell surface adhesions likely exist, including outer membrane proteins and oligosaccharides that work in complement with flagella and pili to promote initial colonization of cell surfaces by *P. aeruginosa*. The CF transmembrane conductance regulator (CFTR) protein also may play an important role as an epithelial cell receptor for *P. aeruginosa*. The CFTR protein appears to be involved with bacterial internalization and clearance from the lung.³²⁶ Diminished internalization of bacteria in murine and primate models of CF might provide some basis for hypersusceptibility of CF patients to infections with *P. aeruginosa*.³²⁶

P. aeruginosa endotoxin is not as potent as are the endotoxins produced by other gram-negative organisms, including *Escherichia coli* (2 to 3 mg is needed to kill a 20-g mouse). The oligosaccharide side chain of *P. aeruginosa* endotoxin prevents lysis by complement and the lipid moiety triggers cytokine pathways that lead to the sepsis syndrome and shock. The virulence of *P. aeruginosa* in a mouse burn model was found to be related directly to lipopolysaccharide integrity.⁸³ Deficiency of the O side chain of lipopolysaccharide reduced virulence markedly.²⁸⁵

Extracellular virulence factors of *P. aeruginosa* include numerous exotoxins with proteolytic or lipolytic activity. These include the elastolytic proteases LasA protease and elastase (LasB), collagenase, gelatinase, caseinase, alkaline protease, fibrinolysin, phospholipase C (a thermolabile hemolysin), lecithinase, exotoxin A, and a group of exoenzymes including ExoS, ExoT, ExoU, and ExoY. The proteolytic enzymes may be responsible for localized necrosis of the skin or lung tissue and for corneal ulceration. The various proteases also can degrade plasma proteins, including complement and coagulation factors.³⁹⁶ Solubilization and destruction of lecithin (surfactant) may play a role in the atelectasis seen in pulmonary infections caused by *P. aeruginosa*. Fibronectin protects epithelial cells from bacterial attachment, but its ability to do so is reduced in patients with CF because of the high level of proteases in respiratory secretions and also after cellular injury from trauma, intubation, or postviral infection.

Exotoxin A is an adenosine-5'-diphosphate ribosyltransferase enzyme that inhibits eukaryotic cell protein synthesis by a mechanism similar to the action of diphtheria toxin. Specific exotoxin A–deficient mutants of *P. aeruginosa* have reduced virulence in mouse and rat models of corneal and lung infection.^{263,394} Exotoxin A also diminishes the activity of host phagocytes. Passive or active immunization against exotoxin A significantly protects against experimental infection with exotoxin A–producing strains of *P. aeruginosa*. Phospholipase C degrades phospholipids, which are plentiful in eukaryotic but not prokaryotic cell membranes. The hemolysis produced by *P. aeruginosa* may be caused by heat-labile phospholipase C and by a heat-stable moiety.

The exoenzymes S, T, U, and Y have multiple enzymatic and chemical functions. Their secretion is regulated by a type III secretion system commonly found in other bacterial pathogens. This system is associated with acute infections, requires pilin-mediated contact with target epithelial cells, and allows the organism to directly inject these products into the host cell cytoplasm rather than simply into the general environment. ExoS and ExoT are bifunctional proteins that display GTPase activation and ADP-ribosyltransferase activity. They confer antiphagocytic activity by depolarizing actin filaments and thus disrupting normal cytoskeletal organization. ExoS also inhibits interleukin production by alveolar macrophages and induces tumor necrosis factor- α production. Production of ExoS is associated with invasive disease in burn patients. *P. aeruginosa* growing on the burn wound but not on intact skin produces ExoS,²⁵⁸ and ExoS can be found in the blood of patients who develop *P. aeruginosa* sepsis before the bacteria can be detected. *P. aeruginosa* strains that do not produce ExoS are less able to cause invasive disease.³¹⁹ ExoU is a potent cytotoxin possessing phospholipase A2 activity and

causing rapid damage to cell membranes and cell death. ExoY has adenylate cyclase activity, but its specific role in virulence is unclear.

The importance of type III secretion proteins in the pathogenicity of *P. aeruginosa* has been demonstrated in animal model systems. Neutralization of these proteins has been shown to prevent septic shock and improve survival in a mouse model system. Similarly antibodies against PcrV, a protein involved in translocation of the exoenzymes, resulted in complete survival of the animals. Rabbit model studies of *P. aeruginosa*-induced septic shock after lung injury also showed the protective effect of antibodies to PcrV.

Among the vast array of proteases produced by *P. aeruginosa*, the elastolytic enzymes LasA and LasB cause direct damage to lung tissue (elastin accounts for 30% of the protein of lung tissue) and can also interfere with immune clearance of *P. aeruginosa* from the lungs. Berger and associates²⁷ noted that elastase treatment of isolated polymorphonuclear leukocytes severely impaired their ability to kill opsonized *P. aeruginosa*. They demonstrated proteolytic degradation of C3b receptors and suggested that it may contribute to the inability of patients with CF to eradicate *P. aeruginosa* from their lungs. Because several cell types, including macrophages, monocytes, B lymphocytes, and some T lymphocytes, carry the same C3b receptor, the proteolytic activity may cleave this molecule from all these cells, thereby decreasing the phagocytic activity of monocytes and macrophages in these patients. Berger and colleagues²⁷ also demonstrated that optimal interaction between the complement-derived opsonic ligands C3b and iC3b and their respective receptors does not occur in the milieu of the lungs of patients with CF who are infected with *P. aeruginosa*. They suggested that both *P. aeruginosa* and host proteases may contribute to the initiation of a cycle of events in which neutrophils entering the infected lung actually impair phagocytosis rather than eradicate the source of infection. Breakdown of elastin in the walls of blood vessels might be responsible for the intrapulmonary hemorrhage noted in individuals with CF.

P. aeruginosa also produces siderophores, including pyoverdine and pyochelin; these are iron-scavenging compounds that allow the organism to replicate in an iron-deficient environment. Iron in host tissue is tightly bound to transferrin or lactoferrin in the lungs. Siderophores bind iron efficiently and then are taken up by the bacterium through cell-specific receptors. Siderophores also play a role in control of expression of other virulence factors.

Mucociliary clearance is impeded in patients with CF, and, as a consequence, they fail to cleanse the bronchopulmonary epithelium of inhaled particles, including bacteria.^{201,250} *P. aeruginosa* adherence to the airways of children with CF may be enhanced by the acidic environment that results from the hyperacidification of the trans-Golgi network from the dysfunctional CFTR protein in lung epithelial cells.²⁸⁹ The specific colonizing strain or strains of *P. aeruginosa* may reflect exposure to other colonized individuals in health care facilities, CF camps, or at home, as well as by selective pressure by the use of mist tents, inhalation therapy, and continuous broad-spectrum antibiotic therapy.^{200,413}

The evolution of colonization from the nonmucoid to the mucoid phenotype of *P. aeruginosa* can be correlated with the patient's age, clinical score, extent of pulmonary function abnormalities, severity of changes on chest radiographs, and serum immunoglobulin levels.^{68,71} The specific lung environment of a patient with CF is believed to trigger a switch to a cluster of genes that code for abundant production of alginate, thereby giving rise to the mucoid phenotype.^{68,348} Strains of *P. aeruginosa* expressing the mucoid phenotype are rarely recovered from patients without CF (0.5%–1.7%). Chronic infection of the lungs in patients with CF selects for additional genetic adaptations by *P. aeruginosa*, including the loss of genes coding for virulence factors (primarily proteins) required for initiation of acute infections.³³⁷ The loss of such virulence factors may contribute to a decrease in the immunogenicity of the organism, a diminished effective immune response, and the inability of the host to eradicate *P. aeruginosa* from the airways.

Persistence of *P. aeruginosa* within the respiratory tract is aided by growth of the organism in microcolonies embedded in a biofilm of alginate.^{164,167,279} This biofilm allows nutrients to pass while protecting the organism from host defense mechanisms, antibodies, and antibiotics.²⁰³ In addition, investigators have noted that rabbit alveolar macrophages

fail to phagocytize and kill the organism in the presence of serum from patients with CF. This phenomenon suggests that these patients have a specific, local defect in pulmonary resistance to *P. aeruginosa*.

The mucoid strains of *P. aeruginosa* isolated from the respiratory secretions of patients with CF produce large quantities of the mucopolysaccharide alginate, which is composed of acetylated D-mannuronic acid and L-glucuronic acid.^{68,347} This polysaccharide polymer not only gives *P. aeruginosa* a mucoid appearance on agar medium but also has antiphagocytic activity. Alginate elicits a significant inflammatory immune response in the lungs of patients with CF and may contribute to the lung damage that occurs in chronic *P. aeruginosa* lung infection.²³⁵ Because of its viscous nature, alginate contributes to the thick bronchial secretions in the lungs of children with CF; these secretions obstruct small airways and impair mucociliary clearance and movement of phagocytic cells. Production of alginate by *P. aeruginosa* is regulated and inducible. Mucoid isolates of *P. aeruginosa* lose the mucoid trait when serially cultured on laboratory media. Nonmucoid isolates convert to the mucoid phenotype when inoculated into the lung in a rat model.²¹⁹ Alginate also inhibits the action of antibiotics.¹⁶³

The predilection for *P. aeruginosa* to colonize and infect the respiratory tract of patients with CF may partially be the result of decreased oxygen tension within the hyperviscous mucous layer.³⁹⁵ Epithelial cells in individuals with CF have increased oxygen usage, which is responsible for the decreased oxygen tension.³⁹⁵ This local hypoxia results in a change in the phenotype of *P. aeruginosa* resulting in alginate production, decreased motility (loss of flagella), and biofilm production.³⁹⁵ Once these phenotypic changes occur, eradication of *P. aeruginosa* from the lungs of individuals with CF is nearly impossible.

The pathogenicity of *P. aeruginosa* also depends on its ability to resist or overwhelm host cell defense mechanisms. Fick and Reynolds^{123,124} noted that in patients with CF, the opsonic function of IgG was reduced as a result of a molecular change in the Fc portion of the immunoglobulin (Ig)G molecule. This deficit was magnified in the lungs of patients with CF infected with *P. aeruginosa* because bacterial proteases can fragment IgG and further impair its opsonic activity. The persistence of *P. aeruginosa* in the lungs of patients with CF also may be related to the presence of one or more factors in their respiratory secretions that interfere with the bactericidal activity of fresh normal human serum against *P. aeruginosa*. These "blocking factors" have been shown to be IgG antibody that inhibit the normal bactericidal activity of human sera IgM antibody.^{282,325}

Concentrations of IgG subclass immunoglobulins have been studied in patients with CF and compared with values obtained in age-matched healthy children and adults. Pressler and associates²⁹⁰ noted that, in 52% of patients with CF, at least one of the four IgG subclasses had an elevated serum concentration in contrast to controls. A significant correlation of elevated serum concentrations of IgG2 (and to a lesser extent IgG3) with decreased forced expiratory volume at 1 second was noted. Moss²⁵¹ found that patients with CF who are infected with *P. aeruginosa* have markedly elevated serum concentrations of IgG antibodies to the opsonic immunodeterminant, type-specific lipopolysaccharide. This elevation was distributed among all four IgG subclasses with a significant shift toward IgG3. Sera from patients with CF who were colonized with *P. aeruginosa* had diminished opsonic capacity, but complement-dependent human neutrophil phagocytosis was not impaired. Serum concentrations of IgG4 but not IgG1, IgG2, or IgG3 are correlated inversely with opsonic capacity. On the basis of these data, Moss²⁵¹ suggested that high levels of IgG4 antibody to opsonic immunodeterminants may inhibit normal pulmonary clearance of *P. aeruginosa* by pulmonary macrophages in vivo. In addition to alterations in humoral immune responses to *P. aeruginosa*, it appears that dysfunctional CFTR also alters the bacterial activity of macrophages against *P. aeruginosa*.⁹⁶

Infection of the lower respiratory tract in patients with CF results in massive infiltration of lung tissue with neutrophils.^{78,105} The neutrophils release elastolytic enzymes that overwhelm the ability of protease-inhibiting compounds of the lung to protect against tissue damage. This results in destruction of lung tissue and accumulation of large amounts of extracellular nucleic acid and cell cytosol matrix, which contributes to airway viscosity.

Virulence factors of other *Pseudomonas* spp., *B. cepacia* complex, and related organisms have been less well studied but include their ability to adhere to indwelling devices and elaboration of exoenzymes such as elastase and gelatinase.²⁵³ *B. cepacia* complex has numerous important virulence factors, some of which play a specific role in the clinical syndromes seen in patients with CF. *P. aeruginosa* enhances subsequent adhesion to epithelial surfaces by *B. cepacia*,³¹³ suggesting a synergistic relationship between the two bacterial pathogens, particularly in patients with CF.³⁴⁴ Additionally, *B. cepacia* complex strains from CF patients with the most severe progression bind most avidly to mucin.³¹⁶ *B. cepacia* also resists nonoxidative neutrophil killing.³⁴⁶ These organisms are intrinsically resistant to many antimicrobial agents. The following host-specific factors increase the risk for colonization with these organisms, as well as progression from colonization to infection: (1) prolonged hospitalization, especially in intensive care settings; (2) administration of broad-spectrum antibiotics³⁴⁸; (3) malignancy, particularly if associated with immunosuppressive therapy and neutropenia^{195,348}; and (4) breaks in mucocutaneous defense barriers, chiefly by instrumentation or the use of invasive devices.¹⁹⁵

As with most pathogens, the pathogenicity of *B. pseudomallei* is related to both virulence factors of the organism and the host's immune response to infection and in many ways resembles the types of infections and clinical outcomes associated with *P. aeruginosa* and to some extent *B. cepacia* complex organisms. As a saprophyte associated with soil and surface waters, the organism can survive harsh environmental conditions, including extremes of temperature, pH, and levels of moisture.⁶³ Moreover the organism also resists the action of many antiseptics, disinfectants, and antibiotics. Altered phenotypes of the organism may be found in culture of clinical material, including small-colony variants with increased antibiotic resistance, as are seen in chronic infection with *P. aeruginosa*.

B. pseudomallei produces a variety of exoenzymes secreted into the environment, including proteases, lipases, lecithinase, phospholipase C, and hemolysins.⁶³ The organism also has type III secretion systems, as are found in many pathogens, including *P. aeruginosa*. These systems allow for delivery of effector molecules directly into host cells and may allow the organism to survive in phagosomes and promote tissue invasion. Interestingly the closely related *B. thailandensis* does not have type III secretion systems and is significantly less virulent. Cell-associated virulence factors include extracellular polysaccharide capsule, lipopolysaccharide, and outer membrane proteins and proteins associated with flagella and pili. As a group, these factors contribute to attachment to epithelial cells and protection against host immune responses, and they

may contribute to biofilm formation. Notwithstanding a wide array of virulence factors, *B. pseudomallei* generally has a low potential for causing disease in humans, as evidenced by the high rates of seropositivity in asymptomatic individuals in endemic areas and the increased likelihood of causing disease in individuals with predisposing factors.⁶³

CLINICAL MANIFESTATIONS

Previously Healthy Children

P. aeruginosa can produce disease in previously healthy, immunocompetent children.^{119,232,264,302,376,392,399} When such infections occur, the source of the organism is water, soil, or vegetative or related contaminated material, and the organism has gained entry through the skin or mucous membrane by a minor or penetrating wound. After entry, the organism may produce a localized infection with cellulitis that may progress to abscess formation and may be associated with a green or blue-green exudate. The skin lesions, whether caused by direct inoculation or secondary to septicemia, begin as pink macules that progress to small cutaneous hemorrhagic nodules and eventually to areas of necrosis, with eschar formation surrounded by an intense red areola (ecthyma gangrenosum, Fig. 125.1).^{252,414} In addition to skin infections, previously healthy children may experience localized and systemic infections, including corneal infection, dacryocystitis, otitis externa, mastoiditis, mastitis, urinary tract infection (UTI), septicemia, endocarditis, bone and joint infections, peritonitis, meningitis, pneumonia, and necrotizing fasciitis.

Outbreaks of dermatitis (folliculitis; "hot tub syndrome"), plantar nodules ("hot foot syndrome"), otitis externa, mastitis, and UTIs caused by *P. aeruginosa* have been reported in normal, healthy children after the use of community swimming pools, water slides, recreational whirlpools, or family-owned hot tubs.^{117,127,149,317,381} Several outbreaks have been described among children using wading pools.^{127,398} Pruritic or painful skin lesions (5 to 30 mm) develop several hours to 5 days or longer (mean, 48 hours) after contact with these water sources. Subcutaneous involvement, including mastitis, has been reported.¹³⁸ Skin lesions may be erythematous, macular, or pustular. In some cases, very tender nodules have been observed. Illness may vary from a few scattered lesions in some patients to extensive truncal involvement in others. The rash is most severe in areas occluded by snug-fitting bathing suits. In some children, malaise, fever, otitis externa, vomiting, sore throat, conjunctivitis, rhinitis, pyuria, abdominal cramps, and swollen breasts may be associated with the dermal lesions. Rarely this recreational

FIG. 125.1 Skin lesion caused by septicemic *Pseudomonas aeruginosa* infection. (A) A large macule has begun to undergo central necrosis and is surrounded by two smaller macules. (B) Small cutaneous nodule representing the skin lesion of septicemic *P. aeruginosa*. (C) Final stage of ecthyma gangrenosum in which a cutaneous hemorrhagic nodule has undergone central necrosis and eschar formation.

water-associated *P. aeruginosa* infection can present with an acute onset of exquisitely painful plantar nodules.^{127,407} Skin biopsy of the tender nodules reveals perivascular and perieccrine neutrophilic infiltrate and microabscesses. Laboratory evaluations reveal leukocytosis with increased proportions of neutrophils and elevations of the sedimentation rate and C-reactive protein.

Multiple serotypes of *P. aeruginosa* have been associated with these outbreaks. The use of whirlpool baths usually involves soaking in water for variable periods. Superhydration of skin and exposure to *P. aeruginosa* result in primary cutaneous infection. Whirlpool water is heated to temperatures above 37.8°C (100°F) and frequently is not filtered, thereby allowing for the persistence of desquamated skin. Both of these factors are conducive to growth of *P. aeruginosa*.

Otitis externa caused by *P. aeruginosa* has been reported in healthy competitive swimmers who swim repetitively in a pool contaminated with *P. aeruginosa*.²⁹⁶ The organism also has been associated with a more malignant form of otitis externa manifested as high fever, necrosis of portions of the external ear, facial nerve paralysis, mastoiditis, and osteomyelitis of the temporal bone and basilar skull.^{169,254} Rarely *P. aeruginosa* meningitis results from progression of this infection.²⁹³ Malignant otitis externa usually is associated with predisposing factors such as malnutrition, leukopenia (a disorder of leukocyte function), malignancy, or diabetes mellitus. Successful management of malignant otitis externa requires surgical debridement in addition to appropriate systemic antibiotic therapy.

P. aeruginosa is a common agent of chronic suppurative otitis media (with or without cholesteatoma) and acute and chronic mastoiditis.²⁴⁵ Chronic suppurative otitis media is a complication of inadequately treated acute otitis media and is manifested as a perforated tympanic membrane with persistent otorrhea. Chronic suppurative otitis media also occurs in children with surgically induced perforations of the tympanic membrane by tympanostomy tubes and incompletely or inadequately treated otitis media. The microbial agents of acute otitis media in children with tympanostomy tubes differ from those in children with intact tympanic membranes. *P. aeruginosa* has been recovered from 12% of children with acute otitis media and tympanostomy tubes.³⁰¹ When tympanostomy tubes become colonized with *P. aeruginosa*, eradication may be complicated by the production of a biofilm.⁴² The presence of a biofilm will reduce effectiveness of conventional systemic and topical antimicrobial therapy. Outpatient therapy with oral antibiotics frequently is unsuccessful because of a lack of oral antimicrobial agents with antipseudomonal activity. Topical ciprofloxacin with or without dexamethasone has been shown to be effective and superior to oral amoxicillin-clavulanic acid in the treatment of acute otitis media in children with otorrhea through tympanostomy tubes.¹⁰¹ Intravenous antibiotics targeting the bacterial agents isolated from middle ear aspirates may be needed to cure chronic suppurative otitis media. This therapy may preclude the necessity of performing tympanomastoid surgery, which becomes essential in those with extensive granulation tissue and osteitis in the mastoid.⁵¹

P. aeruginosa wound infections of the ear have occurred after commercial ear piercing, resulting in perichondritis. Upper ear cartilage is more commonly involved than lobe piercing. In one report reuse of a "single-use" disinfectant bottle contaminated at a sink harboring *P. aeruginosa* was implicated.¹⁹⁰

P. aeruginosa infections of the eye usually occur after minor trauma or surgery, with deposition of a large inoculum topically, or by hematogenous spread. The use of contaminated contact lens solution or the use of tap water during contact lens care, as well as endotracheal suctioning without covering the eyes of sedated or comatose patients have been implicated in dacryocystitis, keratitis, and blepharoconjunctivitis.^{47,160} Use of topical steroids, exposure to contaminated ocular medications, and prior ocular irradiation can predispose to keratitis. Infection of the cornea can result in ulceration, which may progress to more invasive disease, including endophthalmitis.¹⁷³ Most cases of endophthalmitis in children result from penetrating ocular injuries or as a postoperative complication of surgery. Loss of vision may result, even if appropriate antimicrobial therapy is administered promptly.

UTI caused by *P. aeruginosa* occurs rarely in healthy children. More typically, pseudomonal UTI occurs in children who are catheterized,

have had instrumentation or surgery on their urinary tract, who are receiving prophylactic antibiotics, or who were immunocompromised.^{145,230} UTI resulting from *P. aeruginosa* primarily occurs as a result of ascending infection; however, the urinary tract may become infected secondary to bacteremia. The symptoms of pseudomonal UTI are not usually different from those of UTI caused by other bacteria. Because of differing antibiotic susceptibilities of *P. aeruginosa* and the underlying medical condition of the child with a pseudomonal UTI, antimicrobial therapy and clinical response to therapy may differ.

P. aeruginosa is the most common cause of osteomyelitis/osteochondritis after puncture wounds of the foot and is responsible for more than 90% of cases.^{45,113,243} The calcaneus or metatarsal bones commonly are affected. Symptoms may be present for 2 to 40 days (mean, 9 days) before diagnosis is made and hospitalization is needed. Pain and swelling are the most common symptoms; fever and wound drainage rarely are noted. Leukocytosis (white blood cell count >10,000/mm³) and an elevated erythrocyte sedimentation rate are present in most patients.⁸² Radiographs of the affected foot usually show evidence of osteomyelitis at some time during the period of evaluation and treatment. Bone scan results almost universally are abnormal and frequently yield evidence of osteomyelitis before positive findings on radiographs. The inner pad of sneakers has been implicated as a possible source of *P. aeruginosa* in these patients; however, *P. aeruginosa* osteomyelitis of the foot bones has developed when the puncture occurred through other types of footwear or while the child was barefoot.¹²⁸

Other *P. aeruginosa* infections of bones and joints are uncommon findings in children. When they do occur, they are the result of hematogenous spread of *P. aeruginosa* in patients who are intravenous drug abusers, have urinary tract or pelvic infections, or are immunocompromised. Although any bone or joint may be associated with an episode of bacteremia, *P. aeruginosa* has proclivity for the vertebrae, sternoarticular joints, pelvis, and symphysis pubis. The clinical course of *P. aeruginosa* osteomyelitis or septic arthritis is more indolent than that occurring after infection with *Staphylococcus aureus*. Contiguous spread can occur after penetrating trauma, surgery, or overlying soft tissue infections, especially decubitus ulcers.

P. aeruginosa may produce serious infections in healthy neonates. Septicemia may be noted in the earliest hours of life and is associated with high morbidity and mortality. In utero acquisition of the organism resulting in intraamniotic infection (amnionitis), neonatal sepsis, and death has been described.^{260,306,368} The clinical course is similar to that of any other form of gram-negative septicemia, with hypotension, respiratory distress, and skin lesions being the predominant manifestations and high mortality. Late-onset neonatal *P. aeruginosa* infection is more frequent and usually occurs as a nosocomial infection (i.e., bacteremia, UTI, and pneumonia) associated with a foreign body (e.g., indwelling urinary or vascular catheter or endotracheal tube) in hospitalized infants. Outbreaks of *P. aeruginosa* infections in neonatal intensive care units have been associated with infections in health care workers and contaminated milk.^{320,409} Maternal colonization after the use of a hot tub for relaxation during labor was responsible for *P. aeruginosa* meningitis and bacteremia in an 11-day-old infant.³⁸⁰

Other pseudomonads (except *B. pseudomallei*) rarely cause disease in healthy persons. Reports in normal, healthy children, particularly when the children have been hospitalized in an intensive care unit, include pneumonia, keratitis, and abscesses caused by *B. cepacia* complex organisms; abscesses caused by *P. fluorescens*; and otitis media, pneumonia, and osteomyelitis caused by *P. stutzeri*.^{54,142} A penetrating lawn dart injury resulted in a mixed-flora brain abscess with *Sphingomonas paucimobilis*.³⁶⁵ Peritonitis and septicemia caused by *B. cepacia* complex organisms have been associated with contamination of equipment used for peritoneal dialysis.³⁰

Melioidosis is a disease endemic to a large part of South and East Asia and northern Australia.³⁸⁹ Sporadic cases have been described outside of endemic regions, including Africa, Central and South America, and the Caribbean. The causative agent is *B. pseudomallei*, an environmental saprophyte of soil and water in the tropics, particularly in rice paddies. Patients with poorly controlled diabetes, renal disease, or immunocompromised conditions caused by collagen vascular disease, hematologic malignancies, or immunosuppressive therapy appear to

have an increased risk for development of disease after infection with *B. pseudomallei*.²¹⁶

The predominant mode of transmission is via percutaneous inoculation after contact of abrasions or wounds with contaminated soil or water. Infection may also occur after inhalation of contaminated dust or ingestion of contaminated water. An increase in melioidosis cases presenting as pneumonias has been noted after natural disasters associated with heavy rain and winds and during the rainy season.⁶⁷ In the United States, the majority of melioidosis cases have been reported among persons traveling to endemic areas or after occupational exposure, though an autochthonous case has been described in Arizona.^{25,352} Transmission from animals to humans is rare; possible zoonotic cases have been described in endemic areas.⁶⁹ *B. pseudomallei* has also been isolated from abscesses of pet iguanas.⁴¹⁰ An outbreak of melioidosis in Australia was traced to a potable water source from a water treatment plant that had irregularities in purification.¹⁷¹

Most infections with *B. pseudomallei* remain subclinical.²¹⁶ Melioidosis can have a broad spectrum of clinical signs, and symptoms may be latent for months or years before the disease becomes clinically apparent. Classic manifestations of melioidosis include pneumonia and localized skin infections. The initial clinical finding may be a single primary skin lesion (i.e., vesicle, pustule, bulla, or urticaria) in a patient with no underlying disease. Hematogenous spread may follow local infection and multiple abscesses may be noted in every organ of the body. The acute septicemic illness is indistinguishable from other types of septicemia caused by gram-negative organisms. Overall mortality approaches 40%.³⁸⁹ Meningitis; encephalitis; arthritis; nodular pulmonary densities; abscesses of liver, lung, spleen, kidney, and bones; and endophthalmitis have been observed in both normal and compromised hosts after or concomitant with an episode of septicemia.

B. pseudomallei can cause myocarditis, pericarditis, endocarditis, intestinal abscess, cholecystitis, acute gastroenteritis, UTI, septic arthritis, paraspinal abscess, osteomyelitis, hilar lymphadenopathy, and cervical lymphadenopathy. Parotitis was documented in 38% of 126 children with melioidosis in Thailand, none of whom had any apparent predisposition to infection.⁸⁸

Subacute melioidosis generally is characterized by an illness lasting weeks to months. Pulmonary infection in this form of disease is a common occurrence and may mimic tuberculosis. The disease can vary from mild bronchitis to severe, fulminant pneumonitis, and lung consolidation and cavitations occur frequently.²³⁸

Although sepsis and community-acquired pneumonia are common clinical manifestations in adults, children most frequently present with primary cutaneous melioidosis.²³⁶ Cases of neonatal melioidosis have been reported presenting with bacteremia, meningitis, or both caused by *B. pseudomallei*.³⁶⁴ The mode of transmission to these newborn infants is not always clear. Vertical transmission of *B. pseudomallei* has been reported in a woman receiving prednisone for exacerbation of underlying ulcerative colitis during a vacation in Thailand who 6 weeks later gave birth to an infant with sepsis and lung abscess. The infant's blood and endotracheal aspirate cultures yielded *B. pseudomallei*.³ Review of placental histology revealed microabscesses, and postpartum cultures of the mother's cervix grew *B. pseudomallei*. Pulsed-field gel electrophoresis confirmed isolates in the mother and neonate to be a single strain. Cases of mother-to-infant transmission during breastfeeding have also been described in lactating mothers with mastitis.²⁹²

Chronic melioidosis is defined by symptoms persisting beyond 2 months, most commonly from recent acquisition but can also occur from reactivation.⁸⁵ Chronic melioidosis may involve every organ in the body, including the brain.²⁰⁶ Melioidosis may become dormant, with exacerbations occurring years after primary infection when host defenses are impaired as a result of steroid use, burns, diabetes mellitus, or other processes. The longest latent period (24 years) was reported by Kingston.¹⁹⁷

Melioidosis should be considered in any person who has been to Southeast Asia or northern Australia at any time and has fever of unknown origin, overwhelming sepsis, single or multiple abscesses, pneumonia not responding to antibiotic therapy, or any tuberculosis-like illness. The diagnosis is established by culture of blood, skin lesions,

or purulent material from an abscess cavity or from other sites of infection.¹⁶²

Burn Wounds

The surface of burn wounds and skin grafts are frequently colonized by pseudomonads and other gram-negative organisms.¹¹⁹ Colonization does not always progress to infection, but it is a necessary prerequisite to development of invasive disease. Gram-negative bacteria predominate after the fifth day, with *P. aeruginosa* isolated most frequently.^{18,70} Septicemia with *P. aeruginosa* is a major problem in burn patients, with the mortality rates of burn wound sepsis approaching 78%.²³⁷ Systemic involvement may be related to multiplication of organisms in devitalized surface areas with subsequent invasion of healthy tissue and dissemination, or it can be associated with prolonged use of intravenous or urinary catheterization required for the care of these patients. In addition, the hydrotherapy that is provided to burn patients promotes colonization of the burned area and other body sites.³⁶⁶

In burn patients, abnormalities in neutrophil function that precede the onset of septicemia have been described, and killing of *P. aeruginosa* by neutrophils is impaired.¹⁸⁹ Burn injury is also associated with abnormal responses to microbial antigens, delayed rejection of homografts, abnormal vascular responses, impaired delayed hypersensitivity responses, diminished uptake of foreign substances particles by the reticuloendothelial system, and altered antimicrobial pharmacokinetics. Contamination of wounds with high concentrations of bacteria in excess of 10⁵ colony-forming units per gram of tissue impedes contraction and healing of the wound.²⁷⁶ In addition, *P. aeruginosa* produces numerous substances that can further inhibit the natural healing process of burns and wounds. Exogenous plasminogen activators and proteases break down proteins such as fibrin and halt the contraction process.²⁸³ *P. aeruginosa* ExoA, a protein synthesis inhibitor, also contributes to retardation of wound healing.¹⁵⁵ Secondary bacterial infection results in nearly 25% of skin graft loss after full- or split-thickness skin grafts.³⁶⁹ *P. aeruginosa* was responsible for nearly 60% of the infections that resulted in skin graft loss. Skin graft loss was more common when the skin grafts were performed on the lower extremities and when grafts were applied at multiple sites. Furthermore infections of skin grafts with *P. aeruginosa* were more severe and resulted in a fourfold increase in reoperation rates.

Cystic Fibrosis

CF is the most common life-shortening inherited disease among Caucasian children and is caused by mutations in the CFTR gene.⁷⁹ The course and prognosis of disease are determined largely by chronic infection and inflammation of the airways with opportunistic bacteria and death usually resulting from destructive pneumonitis and chronic obstructive pulmonary disease. *P. aeruginosa*, along with *S. aureus*, is one of most prevalent respiratory bacterial pathogens recovered from patients with CF.³¹⁸ A U.S. surveillance study of patients included in the Cystic Fibrosis Foundation reported that 52.5% of patients had *P. aeruginosa* recovered from sputum cultures.²¹⁸ The prevalence varied by age, ranging from 25% for children younger than 5 years to 80% for adults in the 25- to 34-year-old group. Contemporary analysis of the microbiology of sputum in patients with CF also describes an increasing prevalence of aminoglycoside resistance among *P. aeruginosa* isolates.¹¹¹ Initial recovery of *P. aeruginosa* from the respiratory tract of a child with CF may represent colonization and not infection. Colonization is followed by infection, which is intermittent and usually associated with multiple strains of *P. aeruginosa*. At some point, colonization and subsequent infections by a single strain that expresses the mucoid phenotype is the norm, and eradication of the organism with antimicrobial therapy is impossible.^{125,143}

Infection in patients with CF is limited almost entirely to the respiratory tract, and pulmonary exacerbations with endobronchial disease are a common finding.^{90,166} Infection of the pulmonary parenchyma rarely occurs. Rather the epithelium of the airways and the submucosa are edematous and contain infiltrates of chronic inflammatory cells. Documentation of a pulmonary exacerbation in CF relies heavily on clinical impression (e.g., increase in the frequency of productive cough; increase in volume or a change in characteristics of the sputum; increase in the respiratory rate or dyspnea; and decrease in appetite, activity, or

exercise tolerance). Fever and leukocytosis are present in a minority of patients and are associated with poorer pulmonary function test results and a worse prognostic score.³³⁹ However, pulmonary function abnormalities may be present even in the absence of symptoms. Concentrations of *P. aeruginosa*, host cell DNA (derived from polymorphonuclear leukocytes and to a lesser extent from respiratory epithelial cells), and total protein in sputum are increased during pulmonary exacerbations and decrease significantly after antimicrobial therapy.³³⁹ Bronchitis, bronchiolitis, and bronchiectasis can occur. Eventually local necrotizing pneumonitis may be noted, in contrast to the overwhelming generalized necrotizing pneumonitis seen in immunosuppressed patients. Septicemia is a rare occurrence, but *P. aeruginosa* bacteremia may develop in patients with indwelling venous catheters. Colonization of lungs with *P. aeruginosa* after lung transplantation in patients with CF is common and occurs in the early posttransplantation period.²⁰⁵

B. cepacia complex organisms have emerged as agents of asymptomatic colonization, pneumonia, and septicemia in patients with CF. *B. cenocepacia* and *B. multivorans* are the species most frequently isolated from patients with CF in the United States, with *B. multivorans* accounting for the majority of cases. Some members of the complex are more commonly associated with acute clinical deterioration (cepacia syndrome), in particular *B. cenocepacia*^{179,229}; however, other species, such as *B. multivorans*, have also been associated with the cepacia syndrome,³⁷ and *B. dolosa*, an uncommonly encountered species, is associated with a rapid deterioration in lung function and decreased survival.^{53,183}

The prevalence of infection with *B. cepacia* complex organisms in the United States generally ranges from 3% to 4%, with rates as high as 8% having been reported.²¹⁸ Overall the prevalence rates of infection from *B. cepacia* complex in patients with CF have been decreasing.^{218,318} The higher frequency of colonization of the respiratory tract with *B. cepacia* complex in patients with CF has been associated with increased morbidity and mortality rates in some CF centers since the 1980s. The risk for colonization with *B. cepacia* complex increases with the severity of underlying disease and increasing age.³⁵⁹ The source or mode of transmission of the organism has not been defined adequately,^{222,223,360} but person-to-person transmission has been documented.^{148,221} Nosocomial transmission (i.e., patient-to-patient and contaminated inhalation therapy equipment-to-patient) within CF centers and social contact, particularly at summer camps, is one mode of acquisition of new infection. Nonetheless the majority of new infections with *B. cepacia* complex organisms are likely to be the result of acquisition of unrelated strains from the natural environment.

Once colonization with *B. cepacia* complex has been identified in patients with CF, three distinct clinical patterns have been noted: (1) chronic asymptomatic carriage, usually in association with *P. aeruginosa*; (2) progressive deterioration over many months with recurrent acute pulmonary exacerbations accompanied by fever, progressive weight loss, leukocytosis, and an elevated erythrocyte sedimentation rate; and (3) rapid, usually fatal deterioration in pulmonary function associated with necrotizing pneumonia and sometimes bacteremia ("cepacia syndrome").^{172,179,229,253,344} The last complication can occur even in patients whose respiratory status was affected only mildly before acquiring *B. cepacia* complex infection.

Malignancy, Immunosuppression, and Other Predisposing Conditions

Immunosuppressive agents may be used in the management of malignancies, transplantation, or collagen vascular disease. The location of the infectious process and the type of causative organisms depend somewhat on the underlying disease. Infection by *P. aeruginosa*, particularly pneumonia and septicemia, occurs more commonly in children receiving immunosuppressive therapy than in the normal, healthy population.

Children with leukemia, particularly those receiving chemotherapy and those who have neutropenia, are susceptible to septicemia caused by *P. aeruginosa* and other pseudomonads.¹¹⁹ Some pseudomonads, including *P. putida*, have been reported as causes of septicemia in children with malignancy.⁸ Infection generally results from invasion of the bloodstream by a colonizing *Pseudomonas* spp. (e.g., from the gastrointestinal tract). Anorexia, malaise, nausea, vomiting, diarrhea, and fever

may be noted. Generalized vasculitis develops, and hemorrhagic necrotic lesions can be found in all organs, including the skin, where they appear as purple nodules or ecchymotic areas that become gangrenous.²⁹⁵ Other invasive *P. aeruginosa* infections noted in children receiving immunosuppressive chemotherapy include hemorrhagic gangrenous perirectal cellulitis or abscess, typhilitis, preseptal cellulitis, and necrotizing fasciitis.^{241,377} Contemporary mortality rates of 30% have been reported (range, 10–60%).²⁸¹

Children undergoing treatment for malignancies are particularly vulnerable to bacterial infection. The depth of the absolute neutrophil count nadir and duration of severe neutropenia are directly related to the risk of invasive bacterial infection and infection-related mortality in this population. Chemotherapy and radiation therapy also predispose to infections by disrupting protective mucocutaneous barriers and facilitating translocation of pathogens. Fergie and associates⁴¹⁵ described 98 children and adolescents with cancer in whom *P. aeruginosa* bacteremia developed; the rate of bacteremia was highest in patients with leukemia. Most cases occurred when patients had absolute neutrophil counts of less than 100/mm³. Mortality associated with *P. aeruginosa* bacteremia was higher in patients with solid tumors, an absolute neutrophil count of less than 100/mm³, perineal skin lesions, and bacteremia during remission or induction therapy rather than during a relapse.

P. aeruginosa is a major cause of health care–associated infections leading to central line–associated bloodstream infections, catheter-associated UTIs, ventilator associated pneumonias, and surgical site infections.³³⁵ In children, infections are associated with the use of implantable medical devices. Infections of intrathecal baclofen pumps used to manage spasticity have been associated with wound infections and meningitis.⁴⁰⁰ Delayed infections in cochlear implant recipients with *P. aeruginosa* have been reported.¹⁴⁰ *P. aeruginosa* has also been described as a prevalent pathogen causing invasive infections in children with extracorporeal ventricular assist devices.^{52,133} In many cases of device-associated infection, removal of the device is important for successful management of the infection.

P. aeruginosa is a leading cause of nosocomial respiratory tract infection in children receiving inhalation therapy or undergoing mechanical ventilation.^{161,203} Asymptomatic colonization of the upper and lower airways occurs commonly and should be distinguished from respiratory tract disease, tracheitis, and pneumonia. In patients receiving mechanical ventilation, with new or progressive infiltrates on serial chest imaging, respiratory specimens obtained from the endotracheal tube demonstrating a predominance of gram-negative bacilli with an abundance of polymorphonuclear leukocytes on Gram stain in conjunction with a positive culture for *P. aeruginosa*, support the role of *P. aeruginosa* as the causative agent for the lower respiratory tract infection. Absence of *P. aeruginosa* from lower respiratory tract secretions markedly reduces the likelihood that *P. aeruginosa* is in the lower respiratory tract.

Health care–associated *P. aeruginosa* septicemia occurs with increased frequency in children with indwelling vascular or urinary catheters.^{335,355} *Pseudomonas* bloodstream infections associated with the use of contaminated heparin/saline solutions used to flush central venous catheters have also been described in children with underlying malignancies.⁵⁶ *P. aeruginosa* was the second most common pathogen implicated in catheter-associated UTIs, accounting for 11.33% of all cases in the US National Healthcare Safety Network (NHSN) surveillance study from 2009 to 2010.³³⁵ These *P. aeruginosa* strains causing health care–associated UTIs had high antimicrobial resistance rates. An international surveillance study of *P. aeruginosa* clinical isolates from intensive care unit patients from countries in Africa, Asia, Latin America, and Europe reported even higher resistance rates, including 37% resistance to carbapenems.³⁰³ UTIs also have been associated with cystoscopic examination. In addition, septicemia may occur in children with congenital or acquired neutropenia or in persons with a functional deficit in polymorphonuclear leukocyte function. *P. aeruginosa* is a cause of abscesses and meningitis in children with dermoid sinus tracts or dermoids extending down to or communicating with the meninges or neural tissue and in children with myelomeningocele.

Endocarditis caused by *P. aeruginosa* must be considered in children and adolescents with prosthetic valves or other intracardiac synthetic material. The organism also may produce acute or subacute endocarditis

in children with congenital cardiac lesions before or after cardiac surgery and on both native and prosthetic heart valves. Tricuspid valve involvement occurs most commonly, but involvement of multiple valves is possible with *P. aeruginosa*; the manifestations are typical of subacute endocarditis. If the left side of the heart is involved (i.e., aortic or mitral valves), the patient has acute and more fulminant disease. Fever and heart murmur are almost universal findings. Overall infective endocarditis due to *P. aeruginosa* is rare in children. Although traditionally associated with the use of intravenous drugs, hospital-associated *P. aeruginosa* endocarditis is not uncommon.^{21,217,249} Other *Pseudomonas* spp. have been rarely associated with post-cardiac surgery infections.¹²⁹

P. aeruginosa needs to be considered in children and adolescents at risk for acquiring human immunodeficiency virus (HIV) infection, primarily after severe immunodeficiency has occurred.^{130,267,300,343} Risks for acquiring *P. aeruginosa* infection in HIV-infected individuals include hospital exposure, declining CD4⁺ cell count, and the use of dapsone or trimethoprim-sulfamethoxazole (TMP-SMX); azithromycin use was protective.³⁴³ Bacteremia may occur with or without the presence of an indwelling vascular catheter. Fever, hypotension, skin lesions (i.e., papules or ecthyma gangrenosum), and pneumonia are common manifestations.¹³⁰ Children with other severe immune defects are also at risk, and infection may be the initial manifestation of a primary immunodeficiency.²² *P. aeruginosa* supraglottitis has been reported in a 6-month-old child with severe combined immunodeficiency syndrome.²⁰⁹ Mortality rates can be high, particularly when empiric antimicrobial therapy is inadequate for the treatment of severe, invasive *P. aeruginosa* infection.

B. cepacia complex organisms can cause opportunistic infections in patients other than those with CF, primarily in hospitalized or immunocompromised patients. These include nosocomial pneumonia in patients on ventilation, bacteremia, wound infections, UTIs, meningitis, endocarditis, and skin lesions. *B. cepacia* complex organisms are also an important cause of infections in patients with chronic granulomatous disease (CGD) because of the organism's ability to resist killing by defective neutrophils using nonoxidative pathways.³⁰⁴ An 11-year-old Puerto Rican boy with X-linked CGD had documented *B. pseudomallei* lymphadenitis and mediastinitis.¹⁰⁴ Bacteria that cause most infections in CGD are catalase-positive organisms. The CGD-affected neutrophil can kill numerous microorganisms despite its defects because most microorganisms endogenously produce hydrogen peroxide, which the CGD-affected neutrophil can modify and use against the organism in the phagosome. Whereas both *P. aeruginosa* and *B. cepacia* are catalase-positive organisms, the former is a rare pathogen in CGD because CGD neutrophils can kill *P. aeruginosa* organisms by means of nonoxidative mechanisms. Fortunately all of these infections are uncommon findings in children.

P. putida has been primarily associated with health care-associated infection, particularly in the neonatal intensive care unit. Most cases present as bacteremia or as cutaneous infections.^{43,97,210,284,403,405} Cutaneous manifestations reported in neonates with *P. putida* may have an appearance similar to that of staphylococcal scalded skin syndrome.²¹⁰ Mortality rates after infection with *P. putida* are high because of vulnerability of the patients and inappropriate empirical antibiotic therapy. *P. putida* is typically susceptible to antipseudomonal β -lactam antibiotics and carbapenems but not reliably susceptible to aminoglycosides.

P. fluorescens causes disease primarily in immunocompromised patients who have been inadvertently exposed to contaminated infusion fluids, disinfectants, and drinking water.^{110,141,168,194,391} Most infections result in fever; systemic reactions of sepsis and mortality have been reported but are not typical. *P. fluorescens* is usually susceptible to carbapenems, aminoglycosides, and tetracycline; however, *P. fluorescens* is less likely to be susceptible to third-generation cephalosporins and trimethoprim.¹⁶⁸ Mupirocin, a topical antibiotic, is produced through fermentation of *P. fluorescens*.

P. stutzeri has been responsible for a diverse group of clinical conditions, with wound infections being the most common presentation.²⁵⁷ Bacteremia is the second most common presentation and usually results from exposure to contaminated fluids. *P. stutzeri* causing suppurative arthritis and nosocomially acquired brain abscess have been reported in children.^{244,404} Pneumonia, UTI, and skin and eye infections have

also been reported. Most patients with presumed *P. stutzeri* infections are hospitalized and have predisposing conditions that make them vulnerable to opportunistic organism.²⁵⁷ *P. stutzeri* are typically susceptible to antipseudomonal penicillins and cephalosporins, aminoglycosides, and TMP-SMX.

P. mendocina is a recently described opportunistic pathogen.²⁵⁹ Bacteremia, osteomyelitis, subphrenic abscess, meningitis, and wound infections have been reported.^{66,177,259} *P. mendocina* is typically susceptible to carbapenems, third-generation cephalosporins, aminoglycosides, and ciprofloxacin; however, resistance to some or all of these antibiotics has been reported.

P. fulva has been isolated from raw foods and natural environments including rice and petroleum fields but has also recently described as a human pathogen leading to bloodstream and central nervous system (CNS) infections.^{112,331} A *P. fulva* VIM-2 carbapenemase-producing strain causing meningitis was described in a 2-year-old after placement of a drainage system for a neuroectodermal tumor.⁷ Integration of the VIM-2 genes on mobile gene cassettes in this isolate raises concern for possible transmission of resistance cassettes across different *Pseudomonas* species.

Ralstonia spp., especially *R. pickettii*, have caused infections in immunocompromised patients and in those with CF.* *Ralstonia* spp. infections such as catheter-associated bloodstream infections or health care-associated pneumonia have been reported in association with contamination of infusion fluids or respiratory equipment.^{55,57,176,192,208,280}

Ralstonia spp. have been reported to be susceptible to antipseudomonal β -lactams, ciprofloxacin, and TMP-SMX, and some isolates susceptible to aminoglycosides.^{92,411} However, some strains may be resistant to antibiotics typically considered active. Susceptibility testing on clinical organisms is important to guide appropriate therapy. Catheter-associated bloodstream infections may require catheter removal to affect a cure.¹⁹⁹

Most infections with *Cupriavidus* and *Pandoraea* have occurred in immunocompromised individuals or in those with CF. *Cupriavidus* spp. has resulted in bacteremia, skin and wound infections, and respiratory tract colonization or infection.^{17,184,187,212,353,370} *Pandoraea* spp. have been associated with severe lung disease and systemic infection in persons with CF.^{178,180,356} Transmission among patients with CF has been documented.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of *P. aeruginosa* and other pseudomonad infections depends on recovery of the organism from a normally sterile body site such as blood, cerebrospinal fluid (CSF), joint fluid, peritoneal or peritoneal dialysis fluid, or deep tissue obtained in a manner that avoids contamination by cutaneous flora (see previous discussion on etiology). Diagnosis of UTI often requires suprapubic aspiration or urethral catheterization for young children. Purulent material associated with subcutaneous abscesses or areas of cellulitis should be obtained by needle aspiration. A diagnosis of *P. aeruginosa* pneumonia can be made by invasive procedures (i.e., needle aspiration of the lung) and, less convincingly, by recovery of the organism from sputum in a child with CF. Recovery of the organism from the surface of the skin or the throat, a tracheal aspirate, or bronchial secretions may reflect colonization and is not necessarily diagnostic of infection. The validity of a positive culture is enhanced when it is associated with a typical clinical syndrome (e.g., *P. aeruginosa* recovered from a skin lesion typical of "whirlpool" folliculitis). Isolation of *P. aeruginosa* from the respiratory tract, particularly when obtained from an endotracheal tube in an intubated patient, is not an unusual occurrence. Differentiating colonization from infection is clinically important. Gram stain of respiratory secretions obtained by endotracheal suction typically reveals abundant gram-negative rods and polymorphonuclear leukocytes in the setting of a true lower respiratory tract infection caused by *P. aeruginosa* (tracheitis or pneumonitis). An absence of gram-negative rods or the presence of squamous epithelial cells rather than polymorphonuclear leukocytes indicates that either the patient does not have a lower respiratory tract

*References 40, 55, 57, 92, 176, 192, 196, 199, 208, 280, 311, 351, 379, 384, 393.

infection or, if an infection is present, the etiologic agent is not likely to be *P. aeruginosa*.

The presence of bluish, nodular skin lesions and the ulcers with ecchymotic and gangrenous centers and bright areolae (ecthyma gangrenosum) have been considered virtually pathognomonic of *P. aeruginosa* infection. However, ecthyma gangrenosum may be a cutaneous manifestation of other nonpseudomonal bacterial or fungal invasive infections.^{371,385} For example, skin lesions that are clinically indistinguishable from those caused by *P. aeruginosa* have been described after septicemia secondary to *E. coli* and *Aeromonas hydrophila*.^{269,332} Cutaneous or disseminated mold infections, most frequently with *Aspergillus* and *Fusarium* spp. in immunocompromised patients, also can cause the necrotic skin lesions of ecthyma gangrenosum.

Isolation of *Pseudomonas*, *Burkholderia*, and other related species other than *P. aeruginosa* from clinical specimens occurs far less frequently. Recovery of these organisms from sites that normally are sterile, such as blood or blood product containers, always should be considered clinically significant unless proved otherwise.

Serologic testing is not clinically useful for the diagnosis of acute *P. aeruginosa* infection. In contrast, serologic tests may be a useful diagnostic adjunct in melioidosis, particularly in latent or asymptomatic forms of this disease.^{6,256} Hemagglutination, indirect hemagglutination, complement fixation, enzyme linked immunosorbent assay (ELISA), and immunoblot assays have been used.^{15,64,151,152,215} Diagnostic sensitivity of these serologic tests is highly variable. False-negative serology may occur in the setting of acute sepsis. High rates of seropositivity in populations in endemic areas also limit specificity.^{15,64,65,401} Hemagglutination A antibodies generally are present within 7 to 14 days after onset of the illness, whereas the complement fixation test yields positive results in 4 to 6 weeks. Maximal titers for both tests are reached in 4 to 6 months, and detectable antibodies may persist for months to years after initial infection. The indirect hemagglutination test, although not currently available commercially, is a validated and widely accepted assay, used by the Centers for Disease Control and Prevention (CDC) for the diagnosis of melioidosis.⁶² The test uses sheep red blood cells sensitized with *B. pseudomallei* antigens in a microwell format.

The interpretation of all serologic tests for melioidosis is complicated by the fact that there are no generally accepted cutoff values defining acute infection or exposure. Serologic tests are of limited value in patients living in endemic areas because of the rate of seropositivity of such individuals. In fact, the diagnostic performance characteristics of the indirect hemagglutination test has been defined by studies utilizing different cutoffs to take account of the variable rates of background positivity.²⁷⁷ Serology may be valuable in individuals who do not reside in but have recently traveled to endemic areas. Paired sera should be tested whenever possible, but a single high-titer serum sample collected from a patient with a relevant travel history and a clinically consistent clinical presentation may be helpful. Because some individuals with culture-proved melioidosis do not have detectable antibodies, a negative serologic test does not rule out infection.¹⁵³

Several direct antigen detection assays have been developed for the rapid detection of *B. pseudomallei* in clinical specimens. These include latex agglutination, ELISA, or direct fluorescent antibody detection on purulent discharges, blood, or body fluid specimens.^{10,340,402} As with many other antigen detection assays, the sensitivity of these assays precludes their use as stand-alone tests. Reagents for antigen detection tests for *B. pseudomallei* are not available commercially. Gram stain and immunofluorescent stains are simpler and cheaper than antigen detection assays.

PCR and other molecular methods have been used to detect *P. aeruginosa* directly in clinical specimens, particularly in respiratory specimens from patients with CF.^{99,227} Some studies suggest that PCR may be useful in detecting *P. aeruginosa* in sputa of CF patients several months before culture diagnosis and at a time before establishment of chronic infection. This would allow for earlier aggressive antibiotic therapy to eradicate the organisms at a time when eradication may be possible. More recently the application of a quantitative PCR-based protocol directly to samples has been explored. This theoretically will allow sensitive detection along with quantitation of the organism.^{35,214}

Other studies have suggested that PCR performed directly on clinical specimens does not significantly increase detection of *P. aeruginosa* in contrast to culture. In addition, it is difficult to interpret the clinical significance of a positive PCR and a negative culture on the same sample; a false-positive PCR result cannot easily be ruled out. Subsequent culture-confirmed colonization occurring weeks to months later may or may not be due to colonization by the same strain initially "detected" by PCR.

PCR-based and other molecular assays also have been applied to direct detection of pseudomonads other than *P. aeruginosa*, including *B. cepacia* complex organisms and *B. pseudomallei*. The same difficulty in interpreting PCR results for *P. aeruginosa* in patients with CF applies to *B. cepacia* complex organisms. There have been more studies on the diagnostic accuracy of nucleic acid amplification methods for direct detection of *B. pseudomallei* in clinical specimens.^{59,135,182,358} Sensitivity of PCR is highest when performed on specimen types such as body fluids and purulent discharges than on blood, reflective of the bacterial load in the specimen. PCR, when available, may be used as an adjunct to but not a replacement for culture. In addition, molecular detection of resistant genes in *P. aeruginosa* isolates, for example those that produce carbapenemase, is an attractive option for more timely and targeted antimicrobials; however, additional performance and utility data are required.¹²⁶ At this point, molecular assays for the pseudomonads are considered investigational.

TREATMENT

Selection of Antimicrobial Therapy

Suspected or proved systemic infections with *P. aeruginosa* should be treated promptly with empirical antimicrobial therapy. It remains unclear, however, whether monotherapy or combination therapy given as either empiric or definitive treatment is associated with improved clinical outcomes. Although in vitro synergy tests and animal studies have shown potential benefits of combination therapy, much of the clinical data demonstrating that combination therapy is superior to monotherapy are retrospective and have varied design, heterogeneous populations, or methodology flaws including lack of statistical power, or importantly, used suboptimal aminoglycoside therapy in the monotherapy study arm. Contemporary meta-analyses do not find a clinical advantage to combination therapy for pseudomonal infections.^{38,44,270–275} One meta-analysis did not find a mortality benefit to combination therapy, but, when a subanalysis was restricted to *P. aeruginosa* bacteremia in five studies, there was a trend toward reduced mortality with combination therapy; of note, the majority of studies included utilized aminoglycosides in the monotherapy arm.³¹⁰ This effect was not found in other meta-analyses of randomized trials involving 7462 patients, including those with underlying malignancy, fever, and neutropenia; in fact, monotherapy with a broad spectrum β -lactam provided similar survival with less adverse events.²⁷³

The optimal choice of monotherapy versus combination antibiotics remains controversial and the lack of high quality data hampers informed management decisions. In general, however, empiric combination therapy directed at *P. aeruginosa* is a prudent approach for high-risk patients (e.g., patients with neutropenia or burns) who are critically ill or with severe disease (e.g., bacteremia) until the culture and in vitro susceptibility results are known. Mortality rates among patients with infections caused by multidrug-resistant *P. aeruginosa* strains are two- to threefold higher when compared with non-multidrug-resistant strains.³⁶¹ Additionally delayed initiation of appropriate empiric antimicrobial therapy for *P. aeruginosa* bacteremia beyond 2 days directly increased 30-day mortality rates.²⁴⁷ As such, combination therapy is warranted if the individual patient has a history of previous infection or colonization with a multidrug-resistant *P. aeruginosa* strain or if local institutional rates of antimicrobial resistance are high. Two agents with different mechanisms of action, a β -lactam antibiotic and either an aminoglycoside or a fluoroquinolone, are generally chosen for combination therapy. Combination therapy with two β -lactam antibiotics is inappropriate for serious *Pseudomonas* infections because the induction of β -lactamase by one of the agents may result in resistance to both antibiotics. Once antimicrobial susceptibility profiles are available, monotherapy with

a β -lactam agent such as ceftipime, piperacillin-tazobactam, or a carbapenem should be considered in the setting of simple *P. aeruginosa* bacteremia, even in patients with malignancies and neutropenia.¹³⁴ Definitive combination therapy may be warranted for certain infections, such as endocarditis.²¹

Community-acquired *P. aeruginosa* infections are typically susceptible to antipseudomonal penicillins, including penicillin and β -lactamase inhibitor combinations; ceftazidime; ceftipime; carbapenem antibiotics, including meropenem, imipenem, and doripenem, but not ertapenem; aminoglycosides; and quinolone antibiotics, including ciprofloxacin and levofloxacin.¹⁹¹ Susceptibility is less predictable for aztreonam, a monobactam. Strains of *P. aeruginosa* causing health care–associated infections are more likely to be antibiotic-resistant than strains causing community-acquired infections.

Prior use of a specific antibiotic for treatment of infections caused by *P. aeruginosa* may be associated with emergence of resistance.^{109,268} Specifically monotherapy with antipseudomonal β -lactam antibiotics (i.e., antipseudomonal penicillins, cephalosporins, and carbapenems), as well as with the fluoroquinolones, has resulted in selection of resistant mutants during therapy, including selection of multidrug-resistant mutants.^{24,94,268,328}

Table 125.2 provides some of the more commonly prescribed antipseudomonal antibiotics. The dosages of some of these antibiotics may vary with different clinical situations and patient populations. Once-daily administration of an aminoglycoside may decrease nephrotoxicity and improve clinical efficacy. Aminoglycoside doses must be decreased, preferably by increasing the dosing interval, in patients with diminished creatinine clearance (e.g., renal impairment, neonates). Significantly higher doses (e.g., gentamicin or tobramycin 7 to 12 mg/kg per day) may be required for patients with increased total plasma clearance, such as those with CF and burns. Therefore aminoglycoside therapy must be individualized and doses guided by pharmacokinetic information.

Extended-infusion of β -lactam antibiotics (e.g., piperacillin-tazobactam, ceftipime) has been used to extend the time the free drug concentration remains above the minimum inhibitory concentration (MIC) of *P. aeruginosa*, thereby theoretically enhancing bacterial killing.¹⁸⁸ In one series of critically ill patients with *P. aeruginosa* infections, in whom 102 patients received extended infusion dosing of piperacillin/tazobactam versus standard intermittent dosing in 92 patients, the 14-day mortality rate was significantly lower in the extended infusion group compared with the standard intermittent dosing (12% vs. 21%,

respectively; $P = .04$).²²⁵ Noncontrolled data suggest a clinical benefit to this approach but require further prospective study.^{23,115,156,225}

Endocarditis caused by *P. aeruginosa* requires aggressive medical and surgical therapy. Despite combination therapy with maximal β -lactam and aminoglycoside antibiotics, valve replacement (i.e., native and prosthetic) frequently is required for cure. Quinolones should be reserved for patients who are intolerant of aminoglycosides or whose bacteria are resistant to aminoglycosides and has been used in adults for long-term suppression of *P. aeruginosa* prosthetic valve endocarditis.

Meningitis or brain abscess resulting from *P. aeruginosa* may be treated with ceftazidime or ceftipime and should be guided by in vitro susceptibility results. The initial empirical addition of the aminoglycoside or fluoroquinolone should be guided by local susceptibility patterns. Meropenem has good penetration into CSF and can be used as an alternative agent when the *P. aeruginosa* is resistant to cephalosporins. Meropenem is the preferred carbapenem because the high doses of imipenem required to treat CNS infections may be associated with CNS toxicity. Fluoroquinolones such as parenteral ciprofloxacin or the monobactam aztreonam are possible alternative therapies for *P. aeruginosa* CNS meningitis, but experience with these agents for CNS infections in children is limited.^{258,357,367}

Ocular infection with *P. aeruginosa* can be serious and sight-threatening. *P. aeruginosa* corneal ulcerations or keratitis may be seen in contact lens wearers or in intubated, sedated patients in intensive care units. Topical therapy with ticarcillin, piperacillin, tobramycin, gentamicin, amikacin, ciprofloxacin, or ofloxacin may be used and is effective. Clinical efficacy is improved by frequently clearing inflammatory debris and topical application of antibiotics. Initially antibiotic solutions should be administered every 15 to 30 minutes. The frequency can be decreased gradually to four to six times per day when clinical improvement is apparent.

P. aeruginosa endophthalmitis frequently occurs after invasive eye surgery or penetrating ocular injuries. Systemic, topical, and intraocular (i.e., anterior chamber and vitreous cavity) routes may all be required.³⁴⁹ Acute endophthalmitis is a medical emergency, and, even with aggressive medical intervention, return of retinal function is not a common occurrence. The prognosis is worse when initiation of therapy is delayed. Cultures of the vitreous should be obtained as soon as endophthalmitis is suspected. Initial intravitreal therapy for *P. aeruginosa* endophthalmitis should include combination therapy pending culture results. Ceftazidime, imipenem, and ciprofloxacin have greater intraocular penetration than do the aminoglycosides.^{108,167} Adjunctive systemic antibiotics may be required for severe cases.

Chronic suppurative otitis media may be due to a variety of organisms, including *P. aeruginosa*. Obtaining cultures from the middle ear is extremely valuable in determining optimal antimicrobial therapy. In most cases, therapy with a fluoroquinolone available as a topical otic compound (i.e., ciprofloxacin, ofloxacin, or besifloxacin) with or without steroids is effective.³⁷⁵ Because middle ear drainage typically represents perforation of the tympanic membrane, aminoglycoside including neomycin-containing topical therapy should not be used because of potential aminoglycoside ototoxicity. Malignant otitis externa and chronic mastoiditis caused by *P. aeruginosa* require systemic antipseudomonal antibiotic therapy. Surgical debridement also may be required for effective management.

P. aeruginosa folliculitis and plantar nodules generally are self-limited after removal of the exposure and do not usually require specific antimicrobial therapy.¹²⁷ Skin abscesses or abscesses in other locations caused by *P. aeruginosa* should be incised and drained.²⁹⁵ Failure to do so may result in a poor response despite prolonged systemic antibiotic treatment. *P. aeruginosa* may be part of multiorganism infections causing necrotizing fasciitis. Empirical therapy for necrotizing fasciitis should include antibiotics with activity against *P. aeruginosa*. Skin lesions consistent with ecthyma gangrenosum always require empiric antipseudomonal antibiotics.

Osteomyelitis of foot bones from *P. aeruginosa* (e.g., osteochondritis after a puncture wound) requires surgical debridement. Appropriate antipseudomonal antibiotics with a β -lactam or fluoroquinolone for 7 to 14 days after surgery appear to be adequate if infected tissue has been completely removed.¹⁷⁴ Oral ciprofloxacin is an appropriate

TABLE 125.2 Antimicrobial Agents Active Against *Pseudomonas aeruginosa*

^bUncomplicated lower urinary tract infections only.

alternative antibiotic to complete antimicrobial therapy after surgery and evidence of *P. aeruginosa* as a causative agent. The adequacy of surgical debridement of the foot bones and clinical improvement can be monitored by serial sedimentation rates.⁸² *P. aeruginosa* infection of foreign bodies (e.g., vascular, peritoneal, and CNS catheters) may require removal of the foreign material to cure the infection, particularly if a tunnel or exit-site infection exists.

Management of UTIs caused by *P. aeruginosa* will depend on the clinical situation of the infected child, that is, presence or absence of septicemia, instrumentation, and the anatomic location of the infection. In patients with chronic indwelling bladder catheters, isolation of *P. aeruginosa* in a urine specimen may be indicative of bacteriuria alone. In these patients, the bladder catheter should be removed. Whether antibiotics are warranted will depend on results of the new culture and evaluation for consistent symptoms. Symptomatic pseudomonal UTIs should be treated. In patients who are clinically stable and not immunocompromised, a single antibiotic is usually adequate. Antibiotic choices should be guided by antimicrobial susceptibilities. Extended-spectrum cephalosporins, aminoglycosides, carbapenems, aztreonam, and fluoroquinolones are reasonable antibiotic options. In children, more experience exists with extended-spectrum cephalosporins and aminoglycosides. Oral fluoroquinolones may be considered in situations with no systemic infection and an interest in providing nonparenteral therapy. Duration of appropriate antibiotic therapy will vary depending on whether the treatment is for cystitis (5 days) or bacteremia and pyelonephritis (10 to 14 days). Longer duration of therapy may be needed in the presence of systemic infection, complicated pyelonephritis, presence of renal abscesses, or in patients with anatomic or functional abnormalities.

P. aeruginosa may be responsible for lower respiratory tract infections in neonates, infants, children, and adolescents in a variety of settings. The most common manifestations are involvement of the airways in patients with CF and health care–associated tracheitis or pneumonitis in intubated patients. In children without CF with *P. aeruginosa* ventilator-associated tracheitis or pneumonia, shorter courses of antimicrobial therapy, 7 and 8 days, respectively, have proven to be effective.^{61,362} Antimicrobial therapy in CF is aimed at either early eradication of *P. aeruginosa*, treatment of acute pulmonary exacerbations, or maintenance therapy for chronic infections.²⁸⁷ In patients with CF experiencing an exacerbation of pulmonary disease and in critically ill intubated patients in whom *P. aeruginosa* infection is suspected, combination therapy with a β -lactam antibiotic and an aminoglycoside is recommended as empirical treatment. In these patients with a pulmonary exacerbation, combination therapy of a β -lactam plus an aminoglycoside compared with β -lactam therapy alone resulted in longer clinical remission and prolonged time to hospital readmission with a new pulmonary exacerbation.³³⁸ Of note, emergence of tobramycin resistance occurred in both groups, but was more frequent in the combination therapy arm.

The choice of which β -lactam antibiotic and which aminoglycoside to use should be based on the patient's previous antibiotic experience and knowledge of the usual antibiotic susceptibility pattern in the patient's clinical environment. Once susceptibility testing results are known, at least two effective antibiotics should be included in the patient's regimen. The dose and pharmacotherapeutics of the chosen antibiotics should be optimized. If the patient fails to respond to appropriate antibiotic therapy, as evidenced by clinical deterioration, acquisition of antibiotic resistance should be anticipated and additional bacterial cultures should be obtained; one or more of the newer antibiotics should be substituted pending additional susceptibility test results.

After years of antibiotic exposure, patients with CF commonly are infected with strains of *P. aeruginosa* resistant in vitro to achievable blood concentrations of many if not all of the common classes of antimicrobial agents. Moreover penetration of aminoglycosides from blood into respiratory secretions is poor.²⁸ The administration of antibiotics by aerosolization, particularly the aminoglycosides, provides much higher concentrations in respiratory secretions. Inhaled antibiotics have been found to be safe and effective for chronic *P. aeruginosa* lung infections in patients with CF.²²⁸ Administration of aerosolized aminoglycosides to patients with CF resulted in improvement in pulmonary function tests, decreased concentrations of *P. aeruginosa* in sputum,

and no significant apparent toxicity. This aerosol treatment did not increase the isolation of *B. cepacia* complex, *Stenotrophomonas maltophilia*, or *Alcaligenes xylosoxidans*; however, isolation of *Candida albicans* and *Aspergillus* spp. increased.⁴⁹

Aerosolized tobramycin may be used to yield concentrations in respiratory secretions in the range of 100 to 200 $\mu\text{g/mL}$. Some strains of *P. aeruginosa* resistant to blood concentrations of tobramycin may be susceptible to achievable concentrations in respiratory secretions. In vitro susceptibility testing of these organisms may be performed to determine the exact MIC.^{143,248} Limited data exist on the correlation of such in vitro test results and clinical outcome; therefore, in practice, such testing is not commonly performed. In addition to management of resistant *P. aeruginosa*, aerosolized tobramycin given over a prolonged period (>1 year) may have the potential to eradicate *P. aeruginosa* temporarily from CF patients who have newly acquired this organism.²⁹⁴ In patients with CF 6 years of age and older with *P. aeruginosa* persistently present in respiratory airway cultures, the Cystic Fibrosis Foundation recommends the chronic use of inhaled tobramycin in an effort to improve lung function and reduce pulmonary exacerbations.¹³¹ For similar reasons, chronic azithromycin is recommended in children 6 years of age and older.¹³¹ Although the precise mechanism of action of macrolides used for chronic suppressive therapy is unclear, azithromycin seems to have more antiinflammatory properties, including reducing the production of virulence factors, decreasing biofilm production, and having bactericidal effects on *P. aeruginosa* when it is in its stationary (biofilm) phase.²⁰² A randomized, double-blind, controlled trial assessing thrice weekly azithromycin versus placebo demonstrated that children with *P. aeruginosa* who received azithromycin had improvement in their pulmonary FEV₁, less pulmonary exacerbations, and gained more weight than patients who received placebo.³¹⁴ These results did not hold true for children with CF who received azithromycin but were not infected with *P. aeruginosa*.³¹²

Although aztreonam is not approved for use in pediatric patients, inhaled aztreonam has been shown to provide benefit to patients with CF who are colonized with *P. aeruginosa* by improving lung function (improvements in FEV₁), health-related quality of life, and weight.^{234,262,382} Reductions also occurred in bacterial density in sputum. Inhalation of aztreonam had minimal effect on the susceptibility of the patient's *P. aeruginosa* isolates to aztreonam after a course of treatment; however, increases in susceptibility to tobramycin were observed.²⁶¹ Inhaled administration of aztreonam can provide local concentrations of aztreonam in pulmonary mucus that is more than 100 times the MIC₅₀ of the patient's *P. aeruginosa* isolates.¹⁶

Increasing rates of respiratory and invasive infections with multidrug-resistant *P. aeruginosa* in patients with CF and immunodeficient patients, particularly those with malignancies, have resulted in the need to expand antimicrobial options, including reconsideration of older antibiotics. Although the use of polymyxin B and colistin (polymyxin E) has been superseded largely by less toxic agents, they may be useful in selected patients who are infected with strains resistant to the other agents. *P. aeruginosa* is almost always susceptible to these agents (*B. cepacia* complex organisms are resistant). Colistin is available as colistin sulfate, a topical agent or oral preparation (poorly absorbed from the gastrointestinal tract), and colistimethate sodium for parenteral administration. Colistin has retained antimicrobial activity against some multidrug-resistant gram-negative bacteria, including *P. aeruginosa*. During early use of colistin, high rates of nephrotoxicity dampened interest in the drug; however, more recent studies have documented lower rates of nephrotoxicity.^{114,286} Studies in adults have shown safety and efficacy in selected populations against *P. aeruginosa* and other multidrug-resistant gram-negative bacteria.^{33,41,136,150,185,266,307}

In the United States, fluoroquinolones are approved for use in patients younger than 18 years of age to treat complicated UTIs, pyelonephritis, and postexposure treatment for inhalation anthrax. Among the quinolones, ciprofloxacin and levofloxacin are considered antipseudomonal and have been evaluated most often for the treatment of acute and chronic *P. aeruginosa* infection in adolescents and adults with CF.^{305,350} Ciprofloxacin, which may be given orally or intravenously, proved to be effective, as judged by clinical scores and results of pulmonary function tests. Ciprofloxacin may be considered in selected children including

the treatment of multiresistant strains of *P. aeruginosa* and the substitution of an oral quinolone to avoid long-term intravenous therapy requiring an indwelling catheter.

Determining the optimal antibiotic therapy for patients with CF may be problematic. Respiratory cultures often yield different colony morphotypes of *P. aeruginosa*. The various morphotypes may have significantly different antibiotic susceptibility patterns. It is common practice for laboratories supporting the management of patients with CF to individually test multiple morphotypes to include both mucoid and nonmucoid strains.

Antibiotic therapy for *B. cepacia* complex infection is challenging and should be guided by results of in vitro susceptibility testing. Unfortunately, *B. cepacia* is frequently resistant to many commonly used antipseudomonal antibiotic agents, particularly the aminoglycosides. Antibiotics that may have activity against *B. cepacia* include TMP-SMX, minocycline, ceftazidime, antipseudomonal penicillins, antipseudomonal quinolones, and carbapenems; meropenem has greater in vitro activity against *B. cepacia* than imipenem. Typically *B. cepacia* isolates from patients with CF are more antibiotic-resistant than isolates from other patient populations. Combination therapy with two or three antibiotics may be required to achieve a clinical response. Combinations of β -lactam agents with aminoglycosides might provide synergy clinically, even when the *B. cepacia* strain isolated is aminoglycoside-resistant. *B. cepacia* may be susceptible to minocycline.²⁰⁷ Minocycline may be considered to have an adjunctive role in the management of *B. cepacia* infection in patients with CF.

The most active antibiotics against *B. pseudomallei* are imipenem, piperacillin-tazobactam, piperacillin, ceftazidime, ticarcillin-clavulanate, ampicillin-sulbactam, tetracycline, and chloramphenicol.³⁴² Piperacillin, ceftazidime, and imipenem are not bactericidal in vitro. Ciprofloxacin seems to be of limited value because of a high rate of resistance. For acute systemic melioidosis, ceftazidime or meropenem is preferred.³⁸⁷ When third-generation cephalosporins have been used, cefoperazone and ceftazidime have shown greater activity against *B. pseudomallei* than have other third-generation cephalosporin agents. Ceftazidime was compared with chloramphenicol, doxycycline, and TMP-SMX for the treatment of severe melioidosis and was associated with a 50% lower overall mortality rate in contrast to that of other forms of therapy.³⁸⁷ Although the optimal duration of intensive therapy is unknown, generally treatment for a minimum of 14 days is recommended. Intensive therapy lasting 4 to 8 weeks should be provided to patients who are critically ill, with complicated pulmonary disease, with visceral abscesses, and in those with osteoarticular or CNS involvement.

Intensive treatment is followed by eradication therapy with TMP-SMX for at least 12 to 20 weeks to prevent early recrudescence or later relapses of melioidosis.⁸⁶ Some eradication regimens might use amoxicillin-clavulanate, oral fluoroquinolones, or doxycycline, but these portend higher rates of relapse than TMP-SMX-based eradication therapy. Recurrent melioidosis may occur as result of a true relapse or from reinfection and required reinitiation of intensive intravenous therapy, followed by eradication therapy.⁶⁰ Chronic melioidosis can be treated with chloramphenicol, tetracycline, or doxycycline over a period of many months. TMP-SMX was recommended previously, but many strains are resistant.

Mechanisms of Antibiotic Resistance and In Vitro Susceptibility Testing

Antibiotic resistance is an important factor in management of patients with serious pseudomonal infections that do not respond to antibiotic therapy. *P. aeruginosa* shows intrinsic resistance to some antibiotics generally effective against enteric gram-negative rods. This is partly due to the relative impermeability of the outer membrane of *P. aeruginosa*. This membrane is a selective barrier to the uptake of antibiotics. The major porin channel of *P. aeruginosa*, OprF, has a limited number of large channels and other porins, including OprB and OprD, and this limits the rate of passage of molecules the size of antibiotics.²⁶⁸ Aside from the importance of porin channels in resistance or reduced susceptibility to antibiotics, *P. aeruginosa* may show intrinsic resistance to a wide variety of antibiotic classes by the presence of multiple efflux pumps, particularly the resistance modulation systems MexAB-OprM

and MexXY-OprM. Multidrug efflux systems exist in *P. aeruginosa* that can result in expulsion of β -lactams, chloramphenicol, fluoroquinolones, macrolides, novobiocin, sulfonamides, tetracycline, trimethoprim and aminoglycosides.¹²¹ Finally upregulation and overexpression of the intrinsic, inducible chromosomal AmpC β -lactamase renders the organism resistant to ampicillin, amoxicillin, amoxicillin-clavulanate, and first- and second-generation cephalosporins, as well as cefotaxime and ceftriaxone.¹⁶⁵ Thus the high level of intrinsic resistance to antimicrobial agents in *P. aeruginosa* is a combination of several mechanisms acting concurrently.^{46,374}

Aside from intrinsic resistance, *P. aeruginosa* may acquire resistance genes by horizontal transfer from other bacteria by conjugation, transformation, or transduction, as well as by mutational events in the bacterial genome.⁸⁰ For example, *P. aeruginosa* may acquire resistance via acquisition of plasmid-mediated β -lactamases, including extended-spectrum β -lactamases such as the TEM, SHV, VEB, GES, and PER types of enzymes, and metallo- β -lactamases (carbapenemases) such as the IMP and VIM types of enzymes or aminoglycoside-inactivating enzymes (AAC [6']-I and APH [3']-II). Similarly, mutational events in the genome of *P. aeruginosa* may lead to clinical resistance. Hyperproduction of AmpC β -lactamase (encoded by the *ampC* gene) may result from a mutation in the *ampD* gene, whose protein product controls the activity of the AmpR regulator protein. Mutations in genes coding for antibiotic target enzymes such as DNA gyrase/topoisomerase II (*gyrA* and *gyrB*) and topoisomerase IV (*parC* and *parE*) may yield enzymes with reduced fluoroquinolone-binding activity and clinical resistance. Furthermore overexpression of the MexAB-OprM efflux pump as a result of a mutation in the *mexZ* gene may lead to clinical resistance to aminoglycoside, fluoroquinolone, and select antipseudomonal β -lactam antibiotics.^{288,408}

The most clinically relevant β -lactamases produced by *P. aeruginosa* are chromosomally encoded Ambler class C cephalosporinases,²⁹⁸ whose synthesis may be increased on exposure to a number of β -lactam antibiotics (derepression of the *ampC* gene).³²¹ The propensity to induce *ampC* β -lactamase varies among the β -lactam antibiotics, with both cefoxitin and imipenem being strong inducers.^{19,84,107} All antipseudomonal penicillins, cephalosporins (including cephamycins such as cefoxitin), and aztreonam are inactivated to varying degrees by the AmpC β -lactamase produced by *P. aeruginosa*, but cefepime and, to a greater extent, the carbapenems are relatively stable to inactivation.²⁵⁵ *P. aeruginosa* strains harboring the *ampC* gene may produce only low levels of β -lactamase in vitro on initial isolation, and such strains may appear susceptible to β -lactam antibiotics on initial in vitro testing. Once patients colonized or infected with these strains are exposed to β -lactam antibiotics during therapy, induction of β -lactamase production may lead to emergence of resistance. For this reason, repeat in vitro susceptibility testing of additional clinical isolates of *P. aeruginosa* obtained after 48 to 72 hours of appropriate therapy is warranted.

Clavulanate and tazobactam are β -lactamase inhibitors effective against plasmid-encoded Ambler class A β -lactamases, including extended-spectrum β -lactamases found in *P. aeruginosa* and other gram-negative bacteria. However, these β -lactamase inhibitors are not only ineffective against the common AmpC β -lactamase of *P. aeruginosa*, but also are potent β -lactamase inducers. Use of these β -lactamase inhibitors will not enhance the activity of ticarcillin-clavulanate or piperacillin-tazobactam against *P. aeruginosa* and might actually increase the likelihood of emergence of resistant strains.

Whereas imipenem, meropenem, and doripenem resist the β -lactamases commonly produced by *P. aeruginosa*, resistance to carbapenems can result through the loss of an outer-membrane porin that allows carbapenems to enter *Pseudomonas*.⁵⁰ The permeability of other β -lactam antibiotics also may be reduced when this outer-membrane porin is lost. Although chemically distinct from imipenem or meropenem, fluoroquinolones such as ciprofloxacin may induce decreased permeability to both antibiotics.²⁹¹ Plasmid-mediated metallo- β -lactamases that confer resistance to imipenem have been described.^{242,330,383} Fortunately these metallo- β -lactamases are identified only rarely in *P. aeruginosa*.

Ciprofloxacin and levofloxacin are the most effective of the quinolones against *P. aeruginosa*. Alteration of the binding site of DNA gyrase

(plasmid-borne quinolone resistance determinant, *qnr*) and decreased penetration of ciprofloxacin through the *Pseudomonas* cell membrane can result in resistant strains.^{107,213,354}

Tobramycin is the most active aminoglycoside against *P. aeruginosa*, and amikacin induces the lowest frequency of resistant strains. Resistance to aminoglycosides usually results from enzyme-mediated antibiotic modification.¹⁰⁰ The various aminoglycoside-modifying enzymes have different substrate affinities. Therefore resistance to one aminoglycoside through aminoglycoside-modifying enzymes does not predict resistance to others necessarily. Resistance is less common to amikacin than to other aminoglycosides.^{139,406} Aminoglycoside-modifying enzymes usually are coded by plasmid-mediated genes, but they occasionally can be coded by genes on the bacterial chromosome.¹⁰⁰ Plasmid-encoded resistance supports rapid transference among strains within an institution. *P. aeruginosa* also can become resistant to aminoglycosides by decreasing the intracellular uptake of aminoglycosides or by modification of intracellular ribosomal attachment.^{91,107} These mechanisms of resistance generally cause cross-resistance for all aminoglycosides.

In addition to antibiotic resistance, other clinical factors can adversely affect aminoglycoside activity against *Pseudomonas*. The acidic environment in tissue infected with *P. aeruginosa* can inactivate aminoglycosides.³⁹ Aminoglycosides may fail to reach therapeutic tissue levels because of poor penetration into bronchial secretions and lung tissue.²⁸ For patients with tracheitis (e.g., intubated patients) or endobronchial disease (e.g., CF), aminoglycosides and, less frequently, colistin have been administered by aerosol.³²³ This route of delivery allows for greater availability of the antibiotic at the site of the infection, with enhanced safety because of negligible absorption into the systemic circulation. Resistance may emerge after prolonged courses.

Some studies have reported on the accuracy of automated or semiautomated antimicrobial susceptibility test systems and their potential for reporting errors for susceptibility of *P. aeruginosa* to various antibiotics, particularly β -lactam agents.^{81,181,308} The problem appears to be more pronounced with rapid systems that generate a susceptibility result in less than the 18- to 24-hour incubation period used in conventional testing. Such systems have difficulty in detecting resistance against β -lactam agents that may require a minimum time for expression of resistance to a level detectable by phenotypic methods relying on detection of growth. In general, more traditional antimicrobial susceptibility test systems, which include incubation for at least 18 to 24 hours, such as disk diffusion, broth or agar dilution, or epsilon meter test (E-test), produce more reliable results. In one large multicenter study, the agar diffusion methods of disk diffusion and E-test performed acceptably in contrast to a reference broth microdilution method for both mucoid and nonmucoid isolates of *P. aeruginosa* from patients with CF.⁴⁸ In the same study, mucoid isolates were generally found to be more susceptible than nonmucoid isolates. This finding agreed with several other, but not all, studies. The clinical significance of these *in vitro* findings is difficult to interpret given that the mucoid phenotype is thought to be primarily associated with biofilms where antibiotic penetration is compromised. In fact, the role of routine *in vitro* antibiotic susceptibility testing in children with CF as it relates to clinical response and short-term outcomes has been questioned.¹⁷⁰ Not surprisingly, the role of *in vitro* antibiotic synergy testing for multidrug-resistant *P. aeruginosa* has also been questioned because of the lack of standardized testing methods and good outcome data.^{2,132}

The current disk diffusion and MIC interpretative standards (MIC breakpoints) from Clinical Laboratory Standards Institute (CLSI) for susceptibility to *P. aeruginosa*, reflect changes in the breakpoints for piperacillin, ticarcillin, piperacillin-tazobactam, and ticarcillin-clavulanate and breakpoints for the antipseudomonal carbapenem antibiotics (imipenem, meropenem, and doripenem).⁷⁴ The MIC breakpoints for the antipseudomonal penicillin (piperacillin) and penicillin and inhibitor combination antibiotics (piperacillin-tazobactam, ticarcillin-clavulanate) have been changed from the previous breakpoints of 64 $\mu\text{g/mL}$ or less = susceptible (S) and 128 $\mu\text{g/mL}$ or more = resistant (R) to 16 $\mu\text{g/mL}$ or less = S, 32 to 64 $\mu\text{g/mL}$ = intermediate (I), and 128 $\mu\text{g/mL}$ or greater = R. This change was prompted by studies indicating that the likelihood of achieving blood levels of these drugs above 32 or 64 $\mu\text{g/mL}$ for 50% of the time between doses was zero.²²⁵ Indeed some studies suggest that

monotherapy for serious *P. aeruginosa* infection is often ineffective with organisms with such elevated MICs.⁵⁸ Of note, the drug ticarcillin-clavulanate is no longer manufactured in the United States, and, as of the date of writing, there are no new sources of the drug. A newer combination drug, ceftolozane-tazobactam, is available with CLSI breakpoints of 4 $\mu\text{g/mL}$ or less = S, 8 $\mu\text{g/mL}$ = I, and 16 $\mu\text{g/mL}$ or more = R.^{74,116} Similarly the MIC breakpoints against *P. aeruginosa* for doripenem, imipenem and meropenem have been changed from the previous breakpoints of 4 $\mu\text{g/mL}$ or less = S, 8 $\mu\text{g/mL}$ = I, and 16 $\mu\text{g/mL}$ or more = R to 2 $\mu\text{g/mL}$ or less = S, 4 $\mu\text{g/mL}$ = I, and 8 $\mu\text{g/mL}$ or more = R. The revised and more conservative carbapenem breakpoints reportedly allow for better detection of "nonsusceptibility" among isolates of *P. aeruginosa*.

It is important to note that CLSI has published separate MIC breakpoints for other *Pseudomonas* spp. and nonfastidious, glucose-nonfermenting, gram-negative rods, as well as specific MIC breakpoints for *B. cepacia*, *B. pseudomallei*, and selected other related organisms.⁷³ In most cases, breakpoints are available only for a limited number of antibiotics and may not include disk diffusion breakpoints. In general, MIC methods are preferred for such organisms.

PREVENTION

Prevention of infection with pseudomonads depends in part on a continuous surveillance program of the hospital environment that is designed to identify and subsequently eradicate sources of pseudomonads as quickly as possible. Recent updated guidelines provide recommendations for preventing transmission of infectious agents in health care settings and in special populations, such as patients with CF.^{315,334} Transmission of health care-associated *P. aeruginosa* can frequently be traced back to colonization of the health care institution's water distribution system. Biofilm colonization of faucets can be particularly problematic. Pseudomonads can grow to a concentration of 10^6 organisms per milliliter in distilled water that appears to be perfectly clear. Growth of pseudomonads in distilled water, disinfectants, and medications is the factor most commonly incriminated in single-source outbreaks of *Pseudomonas* infection in hospitals. Management of *P. aeruginosa* and other multidrug-resistant organisms in health care settings remains challenging. Recent data from US hospitals report the incidence of *P. aeruginosa* multidrug resistance (MDR) to be 22% among pneumonia isolates and 15% among bloodstream isolates, with MDR isolates being more prevalent than carbapenemase resistant isolates.⁴¹² Thus it is imperative to follow strict infection prevention measures, including good hand hygiene, use of personal protective equipment, and appropriate disinfection and cleaning of equipment and supplies.

Outbreaks of *Pseudomonas* infection in newborn nurseries have been reported.¹⁷⁵ Generally infection has been transmitted by the hands of personnel from washbasin surfaces and suction catheter rinse solution to the newborn infants. Strict attention to hand washing, particularly with a liquid iodophor hand washing agent before and between contact with newborn infants, may prevent or interdict epidemic disease. Daily replacement of all apparatus used for intravenous administration greatly reduces the hazard of extrinsic contamination by *Pseudomonas* and other gram-negative organisms. In addition, meticulous care is required in the preparation of solutions for total parenteral alimentation and in the insertion and care of catheters.

The risk for developing *Pseudomonas* infection in a burn patient also can be minimized by careful protective isolation and by the topical application of silver nitrate (0.5%) solution or 10% mafenide acetate cream. Debridement for removal of devitalized tissue is also imperative. *Pseudomonas* infection of dermal abnormalities that communicate with the cerebrospinal axis can be prevented by careful evaluation and early surgical repair. Providing antibiotic prophylaxis of *Pseudomonas* UTI is difficult without a suitable oral antipseudomonal antibiotic for children. Identification and surgical correction of obstructive lesions of the urinary tract minimize or prevent the development of *Pseudomonas* infection of the urinary tract.

In patients with CF and certain immunocompromised patients, high rates of *P. aeruginosa* colonization and infection and ever-increasing

antibiotic resistance render active or passive immunization (or both) against *P. aeruginosa* desirable. In the past 2 decades, an understanding of the human immune response to *P. aeruginosa* and the immune responses that may provide protection against infection or disease has increased considerably. Naturally occurring immunity generally is ineffective. Certain naturally generated antibodies may even be detrimental.³⁴⁸ These antibodies may form antigen-antibody complexes that increase pulmonary inflammation and direct lung damage. Even if neutralizing antibodies could be administered passively or developed after vaccine administration, the large quantities of mucoid exopolysaccharide produced by *P. aeruginosa* may mask many of the antigens targeted for antibody neutralization or opsonization.

A vaccine against *P. aeruginosa* is a potential preventative strategy for young children with CF but one that, despite years of study, remains a challenge.^{102,333} The significant genotypic and phenotypic variability among *P. aeruginosa* isolates has required testing of multiple antigens. Purified bacterial proteins, including flagellar antigen, outer-membrane proteins, lipopolysaccharide-O, several inactivated bacterial toxins, high-molecular-weight polysaccharide antigen and glycoconjugate, and killed whole-cell vaccine preparations, have been tested. Children with CF infected with *P. aeruginosa* have high levels of IgA, IgG, and IgM antibodies in bronchoalveolar fluid and serum against a variety of potential vaccine antigens compared to uninfected children with CF and healthy control subjects.²⁴⁶ Paradoxically this may interfere with vaccine response. The presence of antibody alone may not be protective enough to prevent infection. The potential impact of a *P. aeruginosa* vaccine also has been suggested as a possible method for preventing or delaying pseudomonal disease in patients with acute leukemia or CF. However, to date, evidence of protective efficacy in humans has not been definitively established for candidate vaccines.

PROGNOSIS

The prognosis of *P. aeruginosa* infection depends on factors related to the host, clinical site of infection, and nature of the underlying disease process. Overall mortality for patients with *P. aeruginosa* bacteremia is approximately 30%, but ranges from 10% to 60%.^{186,265} Risk factors associated with increased risk of mortality from *Pseudomonas* bloodstream infection include: (1) the development of septic shock, (2) inappropriate antibiotic therapy, (3) neutropenia (absolute neutrophil count <500/mm³), and (4) the development of septic metastases.^{36,226,239,324} Some studies have also implicated the presence of multidrug-resistant *P. aeruginosa* strains to negatively impact patient outcomes, although this may also be a surrogate for inappropriate antibiotic therapy.^{89,247,361} Despite an expanded antibiotic armamentarium and improvement in supportive care strategies, *P. aeruginosa* bacteremia continues to be associated with high mortality rates.

Stenotrophomonas (Xanthomonas) maltophilia

Katherine Y. King

Stenotrophomonas maltophilia is an opportunistic pathogen that rarely causes infection in immunocompetent children but causes significant morbidity and mortality among immunocompromised, medically fragile, and interventionized patients. This organism is notable for its intrinsic resistance to many antimicrobial agents.

BACTERIOLOGY AND PATHOGENESIS

A gram-negative bacillus, *S. maltophilia* was previously classified in the *Pseudomonas* and subsequently the *Xanthomonas* genus. It was reassigned as *Stenotrophomonas* in 1993.¹⁰⁰ *S. maltophilia* is an aerobic, nonfermentative, gram-negative bacillus that is lysine decarboxylase-positive. It is generally thought to be oxidase negative; however, up to 20% of isolates were described recently to be oxidase positive.¹⁷ Other key features that allow identification of *S. maltophilia* include oxidation of glucose and maltose, and a positive DNase reaction.⁵² Optimal growth occurs at 35°C (95°F); on sheep blood agar, colonies appear rough and lavender green and have a distinct ammonia-like odor. Morphologically the organism is a straight bacillus, 0.7 to 1.8/μm long, that is motile by means of multiple polar flagella. It grows well on standard culture media, including blood and chocolate agar, and in standard broth blood culture systems. Because of the hardy nature of this organism, standard collection, transport, and storage procedures are sufficient. Isolation from polymicrobial specimens can be achieved by growth on selective media such as MacConkey agar and by the addition of antibiotics such as imipenem, vancomycin, and amphotericin B to the media.⁷³

New molecular techniques for the identification of *S. maltophilia* include use of 16S rDNA sequencing and matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) rapid diagnosis. Early studies suggest that 16S rDNA sequencing provides improved specificity over standard biochemical identification.^{63,84,87,95} In patients with cystic fibrosis

(CF), *S. maltophilia* is occasionally misidentified as *Bordetella cepacia* due to their similar biochemical profiles.¹⁴ Because of the serious clinical implications of misidentification in this group of patients, molecular analysis of the isolates should be considered if biochemical results remain uncertain even after repetition.¹³²

EPIDEMIOLOGY

S. maltophilia is a free-living, ubiquitous organism that naturally lives in water, soil, and plants. Its hearty nature allows it to persist in the hospital environment; it has been cultured from contaminated dialysis fluids,¹² intraocular rinsing solution,⁶⁵ ventilators and other respiratory equipment,^{32,74,109} and preoperative surgical brushes.⁹⁹ Several reports have linked nosocomial outbreaks of *S. maltophilia* to contamination of hospital water sources such as faucet aerators,¹³⁰ taps,¹¹⁰ and sinks,⁷⁴ as well as disinfectant solutions.¹³³ Cases of pseudoinfection caused by contamination of blood collection tubes have been described.¹¹² Person-to-person transmission can occur; cases of nosocomial cross-infection occurring in neonatal and pediatric intensive care units have been described.^{48,57,79} Intestinal colonization with *S. maltophilia* in hospitalized oncology patients with diarrhea could represent a potential source of nosocomial infection.⁶ Because nosocomial outbreaks have been reported, infection control offices should be notified if *S. maltophilia* is isolated.

Predisposing factors associated with colonization and infection by *S. maltophilia* include the presence of a severe, debilitating underlying illness, particularly malignancy; immune suppression (including human immunodeficiency virus infection); hematopoietic stem cell transplantation; exposure to broad-spectrum antibiotics (particularly to carbapenems, quinolones, or broad-spectrum cephalosporins); prolonged exposure to antibiotics; the presence of a central venous catheter (CVC); neutropenia; severe mucositis; prolonged hospital stay; stay in an intensive

care unit; tracheostomy; mechanical ventilation; chronic obstructive pulmonary disease; or a combination of these factors.*

Among children, predisposing factors are similar to those found in adults.¹¹¹ Infection with *S. maltophilia* generally is hospital acquired or health care–associated and is found at higher prevalence in patients with CF.^{49,70,111} *S. maltophilia* is being isolated from clinical samples with increasing frequency.* This increase may be related to the increased number and survival of patients with chronic or complex illness and the increased use of broad-spectrum antibiotics.⁵

PATHOGENESIS

Like many pseudomonads, *S. maltophilia* is an organism with low virulence and limited invasiveness. An intact host immune system is an important deterrent to acquisition of a severe and even life-threatening infection; septicemia and death occur in patients with underlying debilitating illnesses. *S. maltophilia* elaborates a range of extracellular enzymes, including DNase, RNase, fibrinolysin, lipase, hyaluronidase, protease, and elastase, which may play a role in the pathogenesis of disease processes associated with *S. maltophilia*.³¹ The pathogenesis of *S. maltophilia* infection also may be related to the development of cytotoxic activity.⁴⁴ A few specific virulence factors have been studied including YajQ, a cyclic di-GMP binding protein that affects adherence and virulence in a murine infection model.⁴ In addition, *S. maltophilia* has been found to adhere to plastic materials, including intravenous catheters, and to produce biofilm that limits access to both phagocytes and antibiotics, properties that may account for the relatively high incidence of catheter-related bloodstream infections caused by this organism.^{35,31,40} Differences in the *rpf* gene cluster that encodes for the organism's quorum sensing system may account for strain differences in virulence.^{45,66} The *S. maltophilia* genome was published in 2008 and may facilitate future pathogenesis research.²⁶

Colonization with *S. maltophilia*, especially in the respiratory tract, is not an uncommon finding. In debilitated patients, exposure to broad-spectrum antimicrobials, many of which are ineffective against this bacterium, may allow overgrowth of colonizing organisms that subsequently gain access to sterile body sites and cause infection. Portals of infection include indwelling devices such as CVCs, peritoneal dialysis or urinary tract catheters, the respiratory tract, and the gastrointestinal tract. Pathogenesis may also be attributable to the effects of *S. maltophilia* on other bacteria, for example by altering biofilm formation and toxin production by *Pseudomonas aeruginosa*.¹⁰⁶

DIAGNOSIS AND CLINICAL SYNDROMES

The diagnosis of infection is established by isolating the organism from normally sterile sites in the presence of a compatible clinical picture. Importantly, because this organism can survive in the environment and even in hospital equipment such as blood collection tubes and antiseptic solutions, it is important to consider whether growth of *S. maltophilia* in culture represents contamination, colonization, or true infection.

Pneumonia is the most common clinical manifestation of *S. maltophilia* infection. While most pulmonary isolates of *S. maltophilia* represent colonization rather than infection, *S. maltophilia* pneumonia can occur even in the presence of mixed cultures, and it can cause ventilator-associated pneumonia.^{1,46,51,85} Pneumonia can be complicated by septic shock, multiorgan dysfunction, and high mortality, especially if it is accompanied by bacteremia, where attributable mortality has been reported to be 30% to 40%.^{24,38,76,113,114}

S. maltophilia bloodstream infections are usually catheter associated.^{13,74,77,93,125} In a series of 32 episodes of bacteremia in children, 22 were catheter associated.¹¹¹ Primary catheter-associated bacteremia has a good response rate to CVC removal and antibiotic therapy; but secondary bacteremia, which generally occurs in patients who are neutropenic, have concurrent pneumonia, or are critically ill, is associated with a significantly worse outcome.¹³ Bacteremia with this organism has also

been reported in patients following hematopoietic stem cell transplant¹²⁷ and as a complication in burn patients.^{81,119}

Bloodstream infections caused by *S. maltophilia* can be severe. In a pediatric series, 31% of the patients presented in septic shock, and the attributable mortality rate was 6.3%.¹¹¹ In another pediatric series of 32 episodes of bacteremia occurring in 31 children, the crude mortality rate was 40.6%.¹³⁴ In children, the severity of illness appears to be similar regardless of whether *S. maltophilia* is isolated in a monomicrobial or mixed blood culture.¹¹¹ However, the death rate associated with *S. maltophilia* bloodstream infection is, in general, higher in adults.^{74,75,90,93}

Skin and soft tissue infections caused by *S. maltophilia* have occurred in patients who have had work-related injuries and wounds contaminated with soil and plant material, such as lawnmower injuries.^{27,37,54} In the hospital setting, *S. maltophilia* frequently is cultured from wounds and surgical sites, but the clinical significance of this organism in children, particularly when it is isolated in mixed culture, can be difficult to determine.¹¹¹ Tender, erythematous nodular skin lesions have been described in neutropenic cancer patients in association with *S. maltophilia* bacteremia and probably represent metastatic infectious foci.^{117,124,134} *S. maltophilia* has been implicated in the development of ocular infections, including conjunctivitis and keratitis in the setting of ocular surface compromise resulting from trauma, the use of soft contact lenses, or previous infection with human herpes simplex virus.¹⁰⁴ Endophthalmitis and scleritis occurring after ophthalmologic surgical interventions and trauma also have been described.^{21,22,64,71,107}

Other clinical syndromes that have been reported to occur rarely include liver abscesses, cellulitis, meningitis, endocarditis, endophthalmitis, sinusitis, necrotizing ulcerative gingivitis, mastoiditis, chronic diarrhea, peritonitis in patients undergoing peritoneal dialysis, cholangitis, osteochondritis, bursitis, osteomyelitis, and urinary tract infection.* Meningitis is an extremely rare occurrence and may be associated with infection of intraventricular devices,^{96,103} but spontaneous meningitis has been described in a preterm infant.⁸²

S. maltophilia is the fourth most common organism isolated from the bronchial secretions of patients with CF, after *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Haemophilus influenzae*.¹²⁰ The incidence and prevalence of *S. maltophilia* isolated from the respiratory secretions of patients with CF are increasing.^{36,72,108,116} *S. maltophilia* is recovered from the sputum of an estimated 12% of patients with CF in the United States and from as many as 25% of CF patients in Europe.^{108,128} The origin of the bacterium is uncertain; evidence suggests that it may be acquired both in the hospital and in the community.²⁹ Colonization may be transient or persistent, with chronic colonization occurring more frequently in older patients.¹²⁰ Case-control studies identified greater exposure to antipseudomonal antibiotics, oral ciprofloxacin, inhaled aminoglycosides, and oral corticosteroids, as well as more hospitalization days and isolation of *Aspergillus fumigatus* from the sputum as risk factors for colonization with *S. maltophilia*.^{34,86,116} Unlike with *Burkholderia cepacia* infection, no evidence of patient-to-patient transmission of *S. maltophilia* has been found, nor does the organism appear to be associated with rapid deterioration of pulmonary function in patients with CF.^{33,55} Indeed *S. maltophilia* colonization has not been shown to affect 3-year survival in CF patients.⁵⁶

However, *S. maltophilia* colonization has been associated with pulmonary exacerbations in CF patients; patients with chronic *S. maltophilia* infection had a significantly increased risk of pulmonary exacerbation requiring hospitalization and antibiotics compared with patients with no history of *S. maltophilia* (relative risk, 1.63; $P = .0002$).¹²⁹ Thus the clinical significance of isolation of *S. maltophilia* from the sputum of patients with CF and its role in the deterioration in lung function are unclear. Its presence may represent more of a marker of severe, advanced disease rather than a causative agent of respiratory deterioration.^{30,56}

PREVENTION

The rate of person-to-person transmission is low; most transmission occurs due to environmental spread. Therefore environmental

TABLE 126.1 Clinical and Laboratory Standards Institute 2016 Minimum Inhibitory Concentration (MIC) Interpretive Criteria

Agent	Susceptible	Intermediate	Resistant
Trimethoprim-sulfamethoxazole ^a	≤2/38 µg/mL		≥4/76 µg/mL
Ceftazidime	≤8 µg/mL	16 µg/mL	≥32 µg/mL
Chloramphenicol	≤8 µg/mL	16 µg/mL	≥32 µg/mL
Levofloxacin	≤2 µg/mL	4 µg/mL	≥8 µg/mL
Minocycline	≤4 µg/mL	8 µg/mL	≥16 µg/mL
Ticarcillin-clavulanate ^a	≤16/2 µg/mL	32/2 to 64/2 µg/mL	≥128/2 µg/mL

^aSusceptibility for each drug in the combination is noted in the dosage.

decontamination and hospital practices are key in prevention of hospital-associated infections.

TREATMENT

S. maltophilia is inherently resistant to several classes of antibiotics, particularly β-lactams and aminoglycosides.²⁴ Resistance to β-lactams and cephalosporins is mediated by inducible expression of two β-lactamases: L1, a class 3a metallo-β-lactamase, and L2, a serine active-site broad-spectrum cephalosporinase. L1 hydrolyzes a broad range of β-lactam antibiotics, including carbapenems such as imipenem and meropenem.³¹ Other mechanisms of resistance include reduced antibiotic uptake, the main mechanism of aminoglycoside resistance, and an antibiotic efflux system that confers multidrug resistance.^{3,138} The activity of early fluoroquinolones such as ciprofloxacin and ofloxacin varies widely, and emergence of resistance during treatment has been reported.²³ Newer quinolones, including levofloxacin and gatifloxacin, appear to have better activity in vitro against *S. maltophilia*.^{11,43,69,80,131}

Trimethoprim-sulfamethoxazole (TMP-SMX) has been the treatment of choice for *S. maltophilia*^{3,19}; however, it is bacteriostatic and may not be sufficient for some infections or some hosts. Furthermore, due to acquisition of *sul1* and *sul2* genes contained on mobile genetic elements, TMP-SMX resistance has also emerged globally with a recent incidence reported at 17%.^{2,24,42,118} The agents with the best in vitro activity against TMP-SMX-resistant strains are minocycline, tigecycline, and colistin.²⁴ In vitro studies have also suggested that combination therapy using tigecycline and colistin can be synergistic; however, clinical studies have not been done, clinical experience in children is limited, and the proportion of susceptible isolates varies across studies.^{41,42,53,67,68} In vitro antibiotic susceptibility testing is plagued by numerous methodologic problems. Several factors, including the time of incubation and the composition of the medium, affect the interpretation of test results. Furthermore poor reproducibility among different testing methods has been described.^{18,58} Despite these limitations, in cases of serious infection such as bacteremia or severe pneumonia, combination antibiotic therapy should be considered when in vitro and in vivo evidence suggests that rapid emergence of resistance may occur during treatment.^{50,93,122,137}

In cases of catheter-related bloodstream infection, removal of the catheter has been associated with improved outcome, in some circumstances irrespective of the appropriateness of antibiotic therapy, and should be considered for severely ill patients.^{20,38,111,135} Nonetheless successful treatment without removal of the catheter⁹³ has been described.

The Clinical and Laboratory Standards Institute (CLSI) has established standards for antibiotic susceptibility testing, including testing by both disk diffusion and broth or agar dilution (minimum inhibitory concentration [MIC] evaluation).²⁵ For the disk diffusion method, CLSI recommends testing only TMP-SMX, levofloxacin, and minocycline. In the case of broth or agar dilution, 2016 CLSI MIC interpretive criteria are listed in Table 126.1.

Regardless, no controlled clinical studies have determined the most effective antibiotic regimen or duration of treatment, although one study simply concludes that it requires longer treatment than PA or methicillin-resistant *Staphylococcus aureus* (MRSA).⁸³

The relatively new genus of *Aggregatibacter* consists of some former members of the *Haemophilus* and *Actinobacillus* species, including *Aggregatibacter actinomycetemcomitans*, *Aggregatibacter aphrophilus*, and *Aggregatibacter segnis*. *Haemophilus aphrophilus* and *Haemophilus paraphrophilus* were combined into a single species, *Aggregatibacter aphrophilus*, because they were shown to differ only in their requirement for nicotinamide adenine dinucleotide (NAD), also known as V factor. Because the two species were combined into a single species, some *A. aphrophilus* isolates (i.e., formerly *H. paraphrophilus*) are V factor dependent, and others (i.e., formerly *H. aphrophilus*) are not.¹¹

Species of the genus *Aggregatibacter* are nonhemolytic and capnophilic; however, isolates of *A. actinomycetemcomitans* with overexpression of leukotoxin may exhibit a zone of hemolysis. These organisms are involved in a variety of infections, including endocarditis and central nervous system infections. *A. actinomycetemcomitans* is a copathogen in many cases of actinomycosis. It is also strongly implicated as a pathogen in periodontal disease.

These organisms are members of the HACEK group of organisms that have a propensity for infecting heart valves.²⁰ The HACEK group includes *Haemophilus* spp. (except *Haemophilus influenzae*), *Aggregatibacter* spp., *Cardiobacterium* spp., *Eikenella corrodens*, and *Kingella* spp. Endocarditis caused by these organisms usually is insidious, with fever occurring in fewer than 50% of cases.⁹ *A. aphrophilus* is also an important cause of brain abscesses.¹¹ These topics are covered in detail in Chapters 26 and 134 on HACEK endocarditis and *Aggregatibacter aphrophilus*.

AGGREGATIBACTER ACTINOMYCETEMCOMITANS

A. actinomycetemcomitans (formerly *Actinobacillus actinomycetemcomitans*) is a fastidious, non-spore-forming, nonmotile, facultatively anaerobic gram-negative coccobacillus that frequently complicates actinomycosis caused by *Actinomyces israelii*. It is a copathogen in at least 30% of these infections.⁹ Failure to recognize this organism and treat it adequately has resulted in clinical relapse and deterioration of patients infected with actinomycosis.^{10,18}

In addition to being associated with actinomycosis, *A. actinomycetemcomitans* has been implicated as a pathogen in periodontal disease and is part of the oral flora. Periodontitis constitutes a group of oral diseases affecting the supporting soft tissues of the teeth and alveolar bone. Aggressive periodontitis is a group of less frequently occurring but more rapidly progressive forms of periodontitis. These entities are characterized by early age at onset during childhood or adolescence, and there is a propensity for familial involvement. Molar and incisor teeth are affected first in localized aggressive periodontitis that is associated with *A. actinomycetemcomitans*.¹⁵ This is particularly problematic in regions of the world with poor general health.

This organism makes a cytotoxic distending toxin, which is an exotoxin that affects mammalian cells by inhibiting cell division and causing apoptosis.⁵ It also makes a leukotoxin that activates and lyses human leukocytes and induces release of interleukin-1 β from macrophages.⁶ One highly virulent clone is the JP2 genotype, which has highly leukotoxic activity and is strongly associated with aggressive periodontitis.³ *A. actinomycetemcomitans* is also an important pathogen in Papillon-Lefèvre syndrome, an autosomal recessive disorder characterized by prepubertal periodontitis and palmar-plantar hyperkeratosis.¹⁴

A. actinomycetemcomitans can cause pericarditis, meningitis, brain abscess, parotitis, synovitis, osteomyelitis, urinary tract infection, pneumonia, and empyema.⁹ Cases of endophthalmitis,^{1,16} facial cellulitis, and cavernous sinus infection also have been reported.^{7,17} There is increasing evidence of an association between periodontal and cardiovascular diseases. Periodontitis may be an independent risk factor for cardiovascular disease. One study revealed the presence of *A. actinomycetemcomitans* by polymerase chain reaction (PCR) in atheromatous plaques obtained from carotid endarterectomies.⁴ *A. aphrophilus* is also an important cause of brain abscesses.¹²

Most *Aggregatibacter* spp. can be cultured on blood and chocolate agar, but the organisms grow poorly or not at all on MacConkey agar. Some *Aggregatibacter* isolates are cultivatable only on chocolate agar. Cultures require incubation in an enhanced carbon dioxide atmosphere. Since the evolution of continuously monitored blood culture systems with enriched media, extended incubation of blood cultures in cases of HACEK endocarditis is no longer necessary.¹³ The standard 5-day incubation for blood culture bottles is sufficient to detect *Aggregatibacter* spp. and other HACEK organisms. On Gram stain, the organism appears coccoid to coccobacillary.

Aggregatibacter spp. are identified in the laboratory using automated systems, miniaturized biochemical methods (e.g., Remel RapID NH System) or matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometry. 16S rDNA sequencing of heart valve tissue in cases of culture-negative endocarditis has also been used.¹⁹ Because of the frequency of coinfection with this organism in cases of actinomycosis, attempts always should be made to isolate the organism in these patients.

A. actinomycetemcomitans is typically susceptible to the cephalosporins, rifampin, trimethoprim-sulfamethoxazole, aminoglycosides, quinolones, tetracycline, azithromycin, and chloramphenicol. There has been one case report of a brain abscess successfully treated with prolonged meropenem.⁸ *A. actinomycetemcomitans* is also susceptible to penicillin and ampicillin in vitro, but test results do not necessarily correlate with clinical outcomes. Vancomycin, erythromycin, and clindamycin have no activity against this organism. Treatment of aggressive periodontal disease consists of local debridement and antibiotic therapy. Metronidazole and amoxicillin appear to be effective in suppressing *A. actinomycetemcomitans* to below the level of detection.²

Brucellosis

Edward J. Young

Brucellosis is a disease of animals that is transmittable to humans (zoonosis).⁹⁸ Humans are accidental hosts, and human-to-human transmission is rare.¹¹³ Brucellosis is distributed worldwide, and it is estimated that 500,000 human cases occur annually.^{39,101} Programs to eradicate the disease in animals have reduced the incidence of human infection in many countries; however, brucellosis remains enzootic in large parts of the world.^{39,152} Although human brucellosis was once considered rare in childhood, it is now recognized that persons of all ages are susceptible, especially in areas where *Brucella melitensis* is endemic.¹³³

HISTORY

Brucellosis was one of many indistinguishable fevers until 1859, when J.A. Marston, a Royal Army Medical Corps (RAMC) physician, provided the first accurate description of the disease among troops stationed on Malta during the Crimean War. He also observed, "When this form of fever attacks children (which it frequently does), it is apt to leave behind it an enlarged condition of the spleen, difficult to remove."⁸¹

During the 19th century, brucellosis was known by various names, including Mediterranean fever, Malta fever, and undulant fever.⁹³ Although the disease caused considerable morbidity and mortality among British military personnel stationed throughout the Mediterranean, the cause was not immediately apparent. In 1886, David Bruce, another RAMC surgeon, isolated a microorganism from spleen tissue of victims of Malta fever.²² Called *Micrococcus melitensis* (later renamed *B. melitensis*), the organism could be found in the blood, urine, and feces of patients with Malta fever. Between 1904 and 1907, Bruce headed the Mediterranean Fever Commission, which studied aspects of the disease in Malta. Themistocles Zammit, a Maltese physician working with the Commission, first identified native goats as the reservoir of brucellosis and their unpasteurized milk as the vehicle of transmission to humans.¹⁴³ When fresh goat's milk was replaced with tinned condensed milk in the military mess, the incidence of brucellosis among military personnel declined precipitously.¹²⁸ In 1897, Almroth Wright applied the newly devised agglutination assay to the serologic diagnosis of Malta fever.¹⁴⁷

Unlike *B. melitensis*, which was initially isolated from human tissue, other *Brucella* species were recognized because of the diseases they cause in animals. In 1897, Bernhard Bang, a Danish veterinarian, isolated the "abortion bacillus" (later called *Brucella abortus*) from placental tissue of cattle with contagious abortions. *Brucella suis* was isolated from swine in about 1914 by Jacob Traum at the Bureau of Animal Industry.⁶³ In 1918, the bacteriologist Alice Evans recognized the relatedness of these disparate bacteria.⁴⁹ After Evan's work was confirmed, K.F. Meyer and E.B. Shaw proposed the name *Brucella* for the genus to honor Bruce.⁵⁹

Additional species were isolated from sheep (*Brucella ovis*), from desert wood rats (*Brucella neotomae*), and from voles (*Brucella microti*), but none of them have been linked to disease in humans. In 1966,

Carmichael and Brunner²⁶ identified *Brucella canis* as a cause of abortions in kennel-bred dogs; however, it appears to be a rare cause of infection in humans.¹⁴⁴ In the 21st century, previously unrecognized *Brucella* species have been recovered from marine mammals.^{21,57,65} Tentatively named *Brucella cetaceae* (dolphin and porpoise isolates) and *Brucella pinnipediae* (seal isolates), their roles as human pathogens remain to be clarified.^{32,82,123} Another novel strain of *Brucella* (*B. inopinata*) was isolated from a woman with an infected breast implant.^{41,145} With the availability of molecular genetic techniques, it is likely that additional *Brucella* species will be discovered, and the taxonomy of the genus will need continued revision.^{18,51}

ETIOLOGY

The brucellae are small, fastidious, nonmotile, non-spore-forming, gram-negative coccobacilli that lack native plasmids. The outer cell membrane resembles that of other gram-negative bacilli with a dominant lipopolysaccharide (LPS) component. Their metabolism is oxidative, and all strains are aerobic. Some strains require carbon dioxide for growth, especially for primary isolation. Brucellae are always catalase positive, but oxidase activity varies among biovars. Most strains reduce nitrate to nitrite, but some do not. Production of hydrogen sulfide also varies, as does urease activity. A variety of media support the growth of brucellae, including chocolate, trypticase soy, and serum dextrose agars. Growth in vitro is characteristically slow; when brucellosis is suspected, the cultures should not be discarded before 28 days.

Brucellae belong to the α_2 -subdivision of the Proteobacteria; they are phylogenetically related to plant pathogens and symbionts such as *Agrobacterium* and *Rhizobium* and to intracellular animal parasites such as *Bartonella* and *Rickettsia*.³³ On the basis of DNA-DNA hybridization and genome sequencing, the genus *Brucella* comprises a single species.^{42,60,102} Despite genetic homology greater than 90%, the *Brucella* nomen species show a remarkable preference for certain natural hosts. Consequently, the traditional nomen species classification is retained for epidemiologic purposes (Table 28.1).

EPIDEMIOLOGY

Historically in the United States, brucellosis was linked to the livestock industry, and *B. abortus* was the predominant species causing human illness. Farmers, ranchers, abattoir workers, and veterinarians were at highest risk for infection, usually through direct contact with infected animals. With the virtual elimination of bovine brucellosis by way of test-and-slaughter methods and immunization of susceptible cattle, the epidemiology of brucellosis changed, especially in states that border Mexico. *B. melitensis* replaced *B. abortus* as the major cause of human disease, and foodborne transmission replaced direct contact with animals as the primary mode of infection.^{29,138} On the Mexican border, human brucellosis occurs at a rate eight times greater than the national average, and unpasteurized goat's milk cheese is a common

TABLE 28.1 Nomenspecies Classification of *Brucella* spp.

Species	Biovars	Natural Hosts	Pathogenicity for Humans
<i>B. abortus</i>	1-6, 9	Cattle, other Bovidae	Yes
<i>B. melitensis</i>	1-3	Goats, sheep	Yes
<i>B. suis</i>	1-3	Swine	Yes
	4	Reindeer, caribou	Yes
	5	Rodents	Yes
<i>B. canis</i>		Dogs, other canines	Yes
<i>B. neotomae</i>		Desert wood rats	No
<i>B. ovis</i>		Sheep	No
<i>B. pinnipediae</i>		Pinnipeds	Unresolved
<i>B. cetaceae</i>		Cetaceans	Unresolved
<i>B. inopinata</i>		Unresolved	Unresolved (single isolate)
<i>B. microti</i>		Voles, foxes	No

vehicle of transmission.^{47,152,158} Human infection caused by *B. suis* has traditionally been an abattoir-associated infection, but in recent years, hunting of feral swine has become a risk when hunters are contaminated with the blood of infected animals.^{28,131} Personnel working in clinical or research laboratories are also at risk, and brucellosis continues to be the most commonly reported laboratory-associated bacterial infection.^{109,148}

Brucellosis once was thought to be uncommon or mild in children, but susceptibility now is recognized in persons of all ages.¹²⁰ Conditions for the transmission of brucellosis from animals to humans vary among countries and cultures. Where farm animals traditionally are raised in the home, contact with children occurs frequently. Foodborne infection is not limited to any age or sex and can occur without direct contact with animals. Childhood brucellosis occurs more commonly in locations where *B. melitensis* is enzootic, and multiple cases often occur within families.^{11,79,155}

The clinical manifestations of brucellosis in children are not different from those in adults, although unfamiliarity with the disease can delay the diagnosis.^{7,30,121,133} Human-to-human transmission of brucellosis is rare, but venereal transfer has been documented.^{113,130} Rare cases associated with blood or bone marrow transplantation have also been reported.^{2,5,10} Few cases of brucellosis have been reported in patients infected with the human immunodeficiency virus.⁹⁰

Spontaneous abortion is a common manifestation of brucellosis in animals when brucellae localize within the reproductive organs of both sexes. Brucellosis in pregnant women can lead to abortion if unrecognized and untreated.¹¹¹ In a retrospective study from Saudi Arabia, intrauterine death and spontaneous abortion occurred in 46% of 92 women with brucellosis.⁷⁰ This rate was significantly higher than the rate of spontaneous abortion in women without brucellosis. When diagnosed early, pregnant women can be treated successfully without compromising their ability to carry to term or to conceive again.⁷³ On rare occasions, transplacental transmission can lead to neonatal brucellosis.^{24,86,91}

PATHOGENESIS

The incubation period for brucellosis varies, but symptoms typically appear within 2 to 3 weeks after infection. Disease caused by *B. melitensis* or *B. suis* tends to be more severe than that caused by *B. abortus* or *B. canis*.¹³⁸ Morbidity can be considerable, but death occurs in only about 1% of cases, usually from complications such as neurobrucellosis or endocarditis.^{27,152} Although no racial or genetic differences in susceptibility are known in humans, innate immunity has been demonstrated in various animals.⁴⁶

The brucellae lack the usual virulence factors of other bacteria. LPS, the immune-dominant antigen of the cell wall, appears to be the principal mediator of pathogenesis of brucellosis.²⁵ Although 10 to 100 times less toxic than conventional enterobacterial endotoxins such as *Escherichia coli* toxin, brucella LPS functions through the same toll-like receptor 4

(TLR4) pathway and contributes to the organism's ability to survive and replicate within naive mononuclear phagocytes.⁷⁶ The distinctive characteristics of *Brucella* LPS containing long-chain fatty acids have been shown to confer stealth pathogenesis by minimizing the host TLR4-mediated innate immune response.^{25,76,140}

Although humoral antibodies play some role in resistance to infection, the principal mechanism of recovery involves cellular immunity.¹²² Intracellular killing of brucellae occurs when macrophages become activated by specifically committed CD4⁺ and CD8⁺ T lymphocytes. This helper T-cell type 1 (Th1) response involves cytokines, including interferon- γ , interleukin-2, and tumor necrosis factor.¹⁴⁹

CLINICAL MANIFESTATIONS

The spectrum of human brucellosis ranges from subclinical (diagnosed by serology) to chronic (characterized by recurrent symptoms over many years).¹⁵⁶ The disease is characterized by a plethora of nonspecific somatic complaints, such as fatigue, anorexia, nausea, weight loss, sweats, and depression. In contrast, there is a paucity of physical findings, which include fever and occasionally hepatosplenomegaly. The infection can involve any organ or organ system of the body. Sometimes, symptoms related to a single organ predominate, in which case the disease is called *localized*.³⁶ Localization often involves organs rich in elements of the reticuloendothelial system.

Osteoarticular complications are the most frequent localized manifestations of brucellosis, and in children, symptoms of monoarticular arthritis involving the hips, knees, ankles, and sacroiliac joint predominate.^{19,135,137,161} Spondylitis, osteomyelitis, and inflammatory arthropathy have also been described but occur less often in children than adults.^{37,125} Despite advances in imaging techniques, serology and culture remain important for diagnosis.⁶⁶

Neurobrucellosis comprises a variety of nervous system complications, including meningitis or encephalitis, myelitis, radiculitis, peripheral and cranial neuropathies, and demyelinating syndromes.^{53,58,83,116,141} Vasculitis is common,¹⁵⁶ and rare cases of brain abscess and intracerebral granuloma can mimic a neoplasm of the central nervous system.^{48,117} Although most patients complain of headache and weakness, direct invasion of the central nervous system occurs in fewer than 5% of cases.^{20,92} Analysis of cerebrospinal fluid (CSF) in cases of *Brucella* meningitis reveals a lymphocytic pleocytosis, elevated protein levels, and normal or low glucose levels. Organisms are rarely seen on Gram stain or cultured from CSF; however, antibodies to *Brucella* are present, and their finding in CSF is diagnostic.¹² Where available, polymerase chain reaction (PCR) assay of CSF can also confirm the diagnosis.³⁵

Gastrointestinal complaints are common in uncomplicated brucellosis and include anorexia, nausea, vomiting, abdominal discomfort, and weight loss.^{89,119} Rare cases of ileitis,¹⁰⁴ colitis,^{67,132} and peritonitis³ have been reported. As the largest organ of the reticuloendothelial system, the liver is likely always involved in brucellosis even though transaminase levels are only mildly elevated and can be normal.^{36,77} Rarely, acute hepatitis occurs with hepatic enzyme levels resembling viral hepatitis.⁴ Liver histology in patients infected with *B. abortus* is characterized by epithelioid granulomas indistinguishable from sarcoidosis.¹²⁹ In contrast, infection with *B. melitensis* can result in a spectrum of lesions ranging from diffuse hepatitis to granulomas.^{150,153,157} Infection with *B. suis* and *B. melitensis* can also result in a suppurative abscess that may become chronic.^{17,38,142}

Genitourinary tract involvement usually manifests as orchitis or epididymo-orchitis and can be mistaken for testicular cancer.^{61,95} Rare cases of interstitial nephritis, membranous nephropathy, and glomerulonephritis also have been reported.¹⁶⁰

Respiratory tract localization of brucellosis is reported in about 7% of cases.^{97,100,136} Lung lesions attributed to *Brucella* include hilar adenopathy, lobar pneumonia, lung nodules, pleural effusion, and thoracic empyema.⁷⁸ Pleural fluid adenosine deaminase levels may be elevated but are difficult to distinguish from those of tuberculosis.⁴⁴

Cardiovascular lesions of brucellosis include endocarditis, myocarditis, pericarditis, and aneurysms of the aorta and cerebral blood vessels.¹⁰⁷ Native and prosthetic valve forms of endocarditis have been described, with the aortic valve involved most often.^{43,64} Delays in making a

diagnosis can result in life-threatening complications, such as valve rupture, myocardial abscess, and sinus of Valsalva fistulas. Treatment of *Brucella* endocarditis usually requires antibiotics plus valve replacement surgery.^{69,118}

Ocular lesions, most notably uveitis, have been described in patients with brucellosis. Other eye lesions that have been reported include endophthalmitis, optic neuritis, episcleritis, nummular keratitis, and chorioretinitis. The pathogenesis of some lesions is a matter of conjecture because brucellae are rarely isolated from the eye.^{68,110,134}

Cutaneous lesions attributed to brucellosis include contact dermatitis, rashes, abscess, and vasculitis.^{87,88} Occasionally, brucellae have been cultured from subcutaneous papules⁷⁹ and from abscesses.¹⁰⁸ Rarely, brucellosis can result in myositis.^{71,72} Mastitis caused by *Brucella* is not unusual in animals, and it has recently been recognized in humans.^{41,96}

Hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia are common in the course of brucellosis.^{31,40} These changes typically are mild and resolve promptly with antimicrobial therapy. Occasionally, thrombocytopenia can be severe, resulting in hemorrhage into the skin and from mucosal sites.¹⁵⁹ The cause of this complication is likely multifactorial, including hypersplenism, disseminated intravascular coagulation, bone marrow suppression and hemophagocytosis, and immune mechanisms.

DIAGNOSIS

Because the symptoms of brucellosis are nonspecific, the importance of obtaining a detailed history, including occupation, avocations, travel, animal exposure, and food habits, cannot be overemphasized. Routine laboratory tests usually are not helpful, but in the right setting, characteristic hematologic findings (i.e., normal or low white blood cell count) can suggest the possibility of brucellosis.⁸

A definitive diagnosis of brucellosis is made by isolating a specific species of *Brucella* from blood, bone marrow, or other tissue. The rate of positive blood cultures varies from 15% to 70%, depending on the methods used and the period of in vitro incubation.^{56,115} Bone marrow culture is reported to be more sensitive than blood cultures before the introduction of newer isolation techniques.^{45,85} Nucleic acid amplification tests using a variety of gene sequences are being applied with some success to the rapid diagnosis of brucellosis.^{6,55,94,106,146}

In the absence of bacteriologic confirmation, a presumptive diagnosis can be made by measuring the titer of specific antibodies in serum.¹⁵¹ Human brucellosis is characterized by an initial production of immunoglobulin M (IgM) antibodies followed by a switch to IgG synthesis within the second week of infection. Treatment results in a gradual decline in both antibody isotypes; however, the persistence of IgG antibodies is associated with relapse or chronic infection.¹⁰³ The pattern of immunoglobulin isotypes is important for differentiating active from treated disease.^{52,151} This is accomplished by performing the serum agglutination test (SAT) in tandem with 2-mercaptoethanol or dithiothreitol; the latter are disulfide-reducing agents used to block agglutination by IgM while preserving agglutination by IgG.^{23,151} Alternatively, a more direct way to measure IgM and IgG antibodies is the indirect enzyme-linked immunosorbent assay (ELISA) employing anti-IgM and anti-IgG conjugates.^{80,84} Because of problems with commercial IgM enzyme assays, the Centers for Disease Control and Prevention recommends that positive ELISA results be confirmed by agglutination.²⁸

Most serologic tests for brucellosis employ smooth lipopolysaccharide (S-LPS) that can detect antibodies to all smooth species (e.g., *B. abortus*, *B. melitensis*, *B. suis*). Because *B. canis* is naturally rough (i.e., lacks S-LPS), antibodies to this organism require a test using antigen prepared from a rough species (*B. canis* or *B. ovis*).¹⁰⁵ A variety of other cell wall or cytoplasmic proteins have been studied as potential serodiagnostic antigens,⁵⁴ but none has proved superior to LPS-based assays. A latex agglutination assay using S-LPS has been shown to be simple to run, to be rapid, and to have good sensitivity and specificity.¹

TREATMENT

Antimicrobial therapy lessens morbidity, shortens the course of illness, and reduces the incidence of complications of brucellosis.¹⁵⁴ Many drugs

are active against *Brucella* spp., but the results of in vitro sensitivity tests do not always correlate with clinical effectiveness. Because the rate of relapse with single-drug therapy is high, successful treatment requires combination therapy for a prolonged time.^{126,154} The tetracyclines remain the most effective antibiotics against brucellae with minimal inhibitory concentrations less than 1 µg/mL. In vitro killing of brucellae by numerous antibiotics can be enhanced by the addition of an aminoglycoside (i.e., streptomycin or gentamicin).¹¹⁴ Traditionally, the combination of tetracycline administered for 6 weeks plus streptomycin given for 2 to 3 weeks provided the highest cure rates in patients with brucellosis.¹³ Currently, the preferred regimen is doxycycline (200 mg/day given orally for 45 days) plus gentamicin (5 mg/kg per day) as a single daily intramuscular dose for the first 7 to 10 days.^{14,112,124}

Rifampin also shows good in vitro activity against *Brucella* spp., and in 1986, the World Health Organization (WHO) recommended the combination of doxycycline (200 mg/day) plus rifampin (600–900 mg/day) orally for 45 days as the treatment of choice. Although successful for uncomplicated brucellosis, subsequent studies have shown the superiority of the combination of doxycycline plus an aminoglycoside, especially for osteoarticular complications.^{16,127}

Children older than 8 years can be treated similar to adults; however, because tetracycline is contraindicated for children younger than 8 years and for pregnant women, alternative treatments have been sought.¹³⁹ Trimethoprim-sulfamethoxazole (TMP-SMX) in a fixed combination of 80 mg of TMP and 400 mg of SMX (i.e., cotrimoxazole) given twice daily for 45 days plus gentamicin (5 mg/kg/day) as a single daily dose for 7 days has yielded satisfactory results.¹²⁰ Alternatively, the combination of TMP-SMX plus rifampin (15 mg/kg) once daily administered for 6 or 8 weeks gave comparable results.¹¹² Similarly, pregnant women can be treated successfully with TMP-SMX plus rifampin without adverse drug effects on the newborn.⁷⁰

The quinolones are active against *Brucella* spp. in vitro, but the minimal inhibitory concentration values vary for each compound and, to some extent, for *Brucella* isolates.⁵⁰ In clinical practice, however, the results have been disappointing.^{74,75,154} Consequently, quinolones are not recommended as monotherapy for treating brucellosis, and their role in combination therapy awaits well-designed clinical trials.

The optimal treatment of complications of brucellosis such as meningitis and endocarditis has not been defined with certainty.⁹⁹ Doxycycline crosses the blood-brain barrier more effectively than generic tetracycline, and it has been used in combination with other drugs (e.g., rifampin, TMP-SMX) for neurobrucellosis.^{83,92} Third-generation cephalosporins achieve high concentrations in CSF, but the sensitivity of brucellae varies and, in general, β-lactam drugs are not effective when used alone.⁷⁴ Some patients with *Brucella* endocarditis have been treated successfully with the usual antibiotic combination; however, most cases have required additional valve replacement surgery.⁹ For both complications, prolonged therapy is advised.

RELAPSE AND CHRONIC BRUCELOSIS

Most patients with brucellosis recover completely within a few weeks to months after receiving adequate therapy. Despite appropriate treatment, some patients suffer a relapse characterized by recurrence of symptoms and repeat isolation of brucellae from their blood.¹⁵ Relapse is more common if the full course of treatment is not completed, and taking oral antibiotics for 6 weeks can tax a patient's compliance. With few exceptions, relapse is not caused by antibiotic-resistant strains of *Brucella*.^{13,62}

Even with appropriate treatment, some patients experience a delayed recovery and continue to have nonspecific complaints, notably fatigue. These patients have no objective evidence of infection (e.g., fever), and their antibody titers decline as expected. Whether this represents a variant of the chronic fatigue syndrome is not clear, but additional antibiotic therapy does not improve recovery.³⁴ Rarely, chronic brucellosis results from a persistent focus of infection such as osteomyelitis or a deep tissue abscess. These patients have fever or other objective signs of infection, and levels of IgG antibodies in the serum remain elevated. Scanning techniques (e.g., scintigraphy with technetium-99m or gallium-67, computed tomography, magnetic resonance imaging) can be useful in localizing an occult focus of infection.

Pertussis and Other *Bordetella* Infections

129

James D. Cherry • Ulrich Heininger

Pertussis (i.e., whooping cough) is an acute infectious illness of the respiratory tract caused by *Bordetella pertussis* and, less frequently, by *Bordetella parapertussis* and *Bordetella holmesii*.^{89,95,113,123,256,367,399,428,452,617} The illness occurs worldwide and affects all age groups, but it is recognized most often in children, and it is most serious in young, unprotected infants.^{89,106,113,142,251,367,414,426,427,602}

Pertussis due to *B. pertussis* infection is a truly unique contagious respiratory disease.^{109,105,121,269,355,367} The illness (unless complicated by a concomitant or secondary infection) is noninflammatory in nature, and it occurs without significant fever. The paroxysmal cough is different from the cough in all other infectious diseases; it is nonproductive (except for posttussive phlegm), and it is followed by periods of total respiratory normalcy.

HISTORY

Unlike other severe epidemic infectious diseases of children (e.g., smallpox, poliomyelitis, measles), pertussis lacks an ancient history.²⁶⁹ The first observation of pertussis occurred in France in 1414, and the first epidemic was reported in Paris in 1578.^{113,131,319} This epidemic and the clinical characteristics of the cases were described in 1640 by Guillaume de Baillou.

Pertussis was described as the *kink* (a Scottish term synonymous with “fit” or “paroxysm”) and *kindhoest* (a Teutonic word meaning “child’s cough”) in the Middle Ages.^{98,269} In 1669, Sydenham named the illness *pertussis* (meaning “violent cough”).³¹⁹ Isolation of *B. pertussis*, the main causative agent of pertussis, was reported by Bordet and Gengou in 1906.^{49,50}

Vaccines consisting of killed, whole *B. pertussis* organisms were developed soon after the bacterium was isolated, and the first results of protection were reported by Madsen in 1925.³⁵² The mouse protection test, developed and reported by Kendrick and collaborators²⁹⁸ in 1947, allowed vaccine production to be standardized. Comprehensive studies conducted by the British Medical Research Council³⁷⁶ in the 1940s and 1950s demonstrated a correlation between the potency of pertussis vaccines as determined by the mouse protection test and their clinical efficacy in children. As a consequence, immunization against pertussis, most commonly in combination with diphtheria and tetanus toxoids (i.e., DTP vaccine), became part of routine vaccination programs in many countries throughout the world.

Concern about a relationship between pertussis vaccination and temporally associated serious adverse events (i.e., sudden infant death syndrome [SIDS] and a variety of neurologic illnesses) led to a sharp decline in vaccination rates in Japan and several European countries

during the 1970s.^{89,95,109,113,303} Along with well-documented high rates of unpleasant local effects (e.g., swelling, induration) and systemic reactions (mainly fever), concerns about adverse events led to the development of acellular vaccines.

During the 20th century, *B. pertussis* was extensively studied in animal model systems, and many toxins and protective antigens were described.^{109,367,379} A leader in *B. pertussis* research was Margaret Pittman, who was at the National Institutes of Health (NIH) and Food and Drug Administration (FDA) from 1936 to 1990. She published two papers about pertussis toxin (PT) and the concept that pertussis was a toxin-mediated disease.^{453,455} Pittman’s views led to the idea that less reactogenic acellular vaccines could be produced. Sato, who trained at NIH and FDA and was influenced by Pittman, returned to Japan and with colleagues developed the first acellular vaccines (i.e., DTaP vaccines).^{109,494} His goal was to produce a PT toxoid vaccine, but the initial vaccines developed in Japan contained (in addition to toxoided PT) filamentous hemagglutinin (FHA), pertactin (PRN), and fimbria 2 (FIM 2). Although evidence exists that pertussis is not a PT-only illness, the idea persists.^{473,474,552} The most compelling evidence that pertussis from *B. pertussis* infection is not a PT disease is that an identical illness results from infection with *B. parapertussis*, which does not express PT.^{92,256}

In the 1980s, several DTaP vaccines were developed, and phase 2 studies were carried out. In the early 1990s, eight efficacy trials were carried out in Europe and Senegal. The trial vaccines contained different concentrations of one to five antigens. However, all of them were virtually free of lipopolysaccharide (LPS) (i.e., endotoxin), and they were less reactogenic than the whole-cell DTP vaccines. Acellular vaccines (i.e., DTaP vaccines) have been used in Japan since 1981 and in many developed countries since the mid-1990s.^{70,168,244,303,583}

B. bronchiseptica, which causes illness with a cough in several animals and in humans, was first isolated in about 1910 by Ferry¹⁸¹, McGowan,³⁷² and perhaps others who were studying dogs with distemper.³⁶⁷ *B. parapertussis* was isolated first from children with pertussis in the 1930s, and *Bordetella holmesii* was found in nasopharyngeal specimens from patients with pertussis-like illnesses in Massachusetts from 1995 through 1998.^{52,171,170,368,617}

MICROBIOLOGY

The genus *Bordetella* contains 10 species: *B. pertussis*, *B. parapertussis*_{hu} (adapted to humans), *B. parapertussis*_{ov} (ovine-adapted), *B. bronchiseptica*, *Bordetella avium*, *Bordetella hinzii*, *B. holmesii*, *Bordetella trematum*, *B. ansorpii*, and *Bordetella petrii*.^{137,217,256,299,309,367} *B. pertussis* infects exclusively humans. *B. parapertussis* is a human pathogen, but it has also been

From Wirsing von König CH, Riffelmann M, Coenye T. *Bordetella* and related genera. In: Versalovic J, ed. *Manual of Clinical Microbiology*, vol 1. Washington, DC: ASM Press; 1970:739–50.

recovered from sheep (i.e., ovine strains).⁴⁵⁶ Both *B. pertussis* and *B. parapertussis* are respiratory pathogens. *B. bronchiseptica* is primarily an animal pathogen that causes atrophic rhinitis and pneumonia in pigs, kennel cough in dogs, pneumonia in cats, and respiratory illnesses in other animals.^{137,206,536} This organism also is the occasional cause of respiratory illness in humans.^{51,126,149,219,424,519,536,537,612} *B. avium* is an important cause of respiratory illness in turkeys and other birds.³⁰⁰

In addition to *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica*, five other species have been recognized to infect or colonize humans.* *B. holmesii* and *B. hinzii* have been isolated from blood cultures, primarily in patients with underlying chronic illness. *B. holmesii* also has been isolated from the human respiratory tract, as has *B. hinzii* and *B. petrii* in patients with cystic fibrosis, and *B. trematum* has been found in wounds and ear infections. *B. ansorpii* has been isolated from a cyst in an immunocompromised 19-year-old girl.³⁰⁹ *B. petrii* has been isolated from the environment and is capable of anaerobic growth.⁵⁷³

The genus *Bordetella* consists of gram-negative, pleomorphic, aerobic bacilli that are grouped together on the basis of genotypic characteristics; species are differentiated by phenotypic characteristics. Selected differential characteristics of the four *Bordetella* spp. that cause respiratory illnesses in humans are given in Table 129.1. All species have relatively simple requirements, but *B. pertussis* is quite fastidious and is inhibited by constituents in common laboratory media such as fatty acids, metal ions, sulfides, and peroxides.^{563,605} For laboratory growth, *B. pertussis* requires the addition of protective substances such as charcoal, blood, or starch. Other species are less fastidious and may grow in blood or MacConkey agars.

More than a decade ago, the genomes of representative strains of *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* were sequenced.^{68,446,460} The genome sizes are as follows: *B. pertussis* has 4,086,186 base pairs (bp); *B. parapertussis* has 4,773,551 bp; and *B. bronchiseptica* has 5,338,400 bp. *B. pertussis* has 3816 predicted genes, whereas *B. parapertussis* and *B. bronchiseptica* have 4404 and 5007 predicted genes, respectively. Pseudogenes occur most commonly in *B. pertussis* (358) and *B. parapertussis* (220) and are uncommon in *B. bronchiseptica* (18). *B. pertussis* has three insertion sequence (IS) elements: IS 481 (238 copies), IS 1002 (6 copies), and IS 1663 (17 copies). *B. parapertussis* has IS 1001 (22 copies) and IS 1002 (90 copies). The sequenced *B. bronchiseptica* RB50 strain contained no IS elements, but studies of other *B. bronchiseptica* strains found strains with IS 481, IS 1001, and IS 1663.^{157,192,344,468,546} Recently, the genomes of other *B. pertussis* strains and strains of *B. holmesii*, *B. avium*, and *B. hinzii* have been sequenced.^{240,403,445,467}

ETIOLOGY OF PERTUSSIS (WHOOPIING COUGH)

B. pertussis and *B. parapertussis* are the usual etiologic agents of pertussis, but 86% to 95% of illnesses are caused by *B. pertussis*.^{123,208,256,459} In rare instances, *B. bronchiseptica*, which normally is enzootic in pigs, dogs, cats, rodents, and other animals, has been isolated from humans with pertussis-like illnesses.^{51,126,149,219,424,519,536,537,612} From 1995 to 1998,

B. holmesii was isolated from the nasopharynx of 33 individuals in Massachusetts with suspected pertussis; most of them were adolescents or young adults.³⁶⁸ Since then, *B. holmesii* has been identified by polymerase chain reaction (PCR) from the nasopharynx of coughing patients in an increasing number of countries.^{451,452} Unlike all other *Bordetella* spp., this organism is susceptible to cephalixin, an antibiotic that frequently is added to *Bordetella* culture media.⁴³¹ This addition may explain why the organism was not previously identified in patients with pertussis in culture-based laboratory studies.

Adenoviruses have been isolated from children with pertussis, and some researchers have suggested that several adenoviral types may on occasion cause a pertussis-like illness.^{26,130,132,420} However, the data of Nelson and associates¹²⁰ and Baraff and coworkers,²⁶ as well as our own observations, lead us to suggest that mixed infections are occurring and that the classic symptoms are caused by *B. pertussis* and not by infection with an adenovirus. Similarly, coinfection with respiratory syncytial virus (RSV) may occur, but the classic symptoms are caused by *B. pertussis*.²⁴⁵ Wirsing von König and associates⁶⁰⁶ observed pertussis-like illnesses caused by viral or *Mycoplasma pneumoniae* infections in 83 patients for whom pertussis laboratory studies were negative. The authors serologically identified 33 adenoviral illnesses, 18 illnesses caused by parainfluenza viruses, 15 illnesses caused by *M. pneumoniae*, and 14 caused by RSV. Wang and colleagues⁵⁷⁷ retrospectively studied prolonged illness with cough in 179 children and found that 37% had evidence of *B. pertussis* infection and 13% had *M. pneumoniae* infections. The cough duration in those with *M. pneumoniae* was significantly shorter (median, 39 days) than in children with *B. pertussis* infections (median, 118 days). In young infants, coinfection with an adenovirus and perhaps RSV may lead to more severe disease.^{36,328} Zouari and associates⁶²⁴ identified *B. pertussis* and *M. pneumoniae* coinfections in three fatal cases in young infants.

Infection with human bocavirus also may cause an illness with a paroxysmal cough.¹⁹ Of 54 children with laboratory-confirmed bocavirus infections, 85% had cough and 19% had paroxysmal coughing episodes.

Physicians often suggest that *Chlamydia trachomatis* can cause a pertussis-like illness. However, the repetitive cough of *C. trachomatis* is distinctly different from the paroxysmal cough of *B. pertussis* infection, and illnesses caused by the two agents usually should not be confused clinically. Infections with *Chlamydia pneumoniae* and *M. pneumoniae* also cause long-lasting illness with cough.^{145,228,571,606} Although infection with these agents in older children and adults can be confused with *B. pertussis* infection, true paroxysms typical of pertussis rarely occur.

ANTIGENIC AND BIOLOGICALLY ACTIVE COMPONENTS OF *BORDETELLA PERTUSSIS*

B. pertussis contains a variety of components that are thought to be antigenic or biologically active.* All known virulence factors produced

*References 20, 135, 146, 161, 193, 194, 239, 279, 292, 294, 296, 322, 337, 341, 368, 398, 399, 418, 420, 444, 516, 518, 541, 561, 594, 617.

TABLE 129.2 Biologically Active and Antigenic Components of *Bordetella pertussis* That Have a Role in Human Infections or Illness

Component	Characteristic
Pertussis toxin (PT) (i.e., lymphocytosis-promoting factor)	A classic bacterial toxin with an enzymatically active A subunit and a B oligomer-binding protein; effects in an animal model system include histamine sensitization, promotion of lymphocytosis, stimulation of insulin secretion, and adjuvant and mitogenic activity; the envelope protein is also an important adhesin; it adversely affects host immune cell function
Adenylate cyclase toxin (ACT)	Calmodulin-activated RTX ^a family toxin with dual adenylate cyclase and hemolysin activity; acts as an antiphagocytic factor during infection
Fimbriae (FIMs)	Serologic types 2 and 3; antibody to specific types causes agglutination of the organism; organisms may contain FIM 2, FIM 3, FIMs 2 and 3, or neither form
Filamentous hemagglutinin (FHA)	220-kd surface-associated and secreted protein; highly immunogenic
Lipopolysaccharide (LPS) (i.e., endotoxin)	An enveloped toxin with activities similar to endotoxins of other gram-negative bacteria; a significant cause of reactions to whole-cell pertussis vaccines; antibody to LPS causes agglutination of the organism
Autotransporters	
Pertactin (PRN)	69-kd outer-membrane protein that allows the organism to resist neutrophil-mediated clearance; antibody to pertactin causes agglutination of the organism
Vag8	95-kd outer-membrane protein
BrkA	73-kd surface-associated N-terminal passenger domain with 30-kd outer-membrane C-terminal protein; confers serum resistance and protection against antimicrobial peptides in <i>B. pertussis</i>
SphB1	Subtilisin-like Ser protease or lipoprotein required for FHA maturation
Tracheal colonization factor (i.e., <i>tcfA</i> gene product)	60-kd secreted protein

^aThe RTX toxin superfamily is a group of cytolytins and cytotoxins produced by bacteria. The name RTX (i.e., repeats in toxin) refers to the glycine- and aspartate-rich repeats at the C-terminus that facilitate toxin export.

by *B. pertussis* are regulated by the single genetic locus *bvgAS*.¹³⁷ Under certain conditions, such as an environmental temperature of 37°C, *bvgAS* is active, toxins and biologically active surface proteins are produced, and the organism is virulent in a mouse model (i.e., *bvg*⁺ phase). In the *bvg*⁻ phase, a different set of genes (i.e., *vrg* and *vir* repressed genes) are expressed, and *B. pertussis* is avirulent in mice in this phase.⁵⁸⁸ The switch from *bvg*⁺ to *bvg*⁻ is a phenomenon common to all *Bordetella* spp. and is associated with a change in phenotype. An intermediate phase with reduced virulence and expression of specific proteins also has been characterized. It has been speculated that the intermediate phase may have some function in transmission of the organism.^{137,525} Since its original isolation in 1906, *B. pertussis* has been extensively studied by microbiologists, molecular microbiologists, epidemiologists, and clinicians.^{49,106,109,121,367,379,444} Vast numbers of studies were carried out in mice. Of most importance were the studies of what now is called PT during the past 65 years. During the past 45 years, additional biologically active proteins, which were thought to be virulence factors, were discovered. The various alleged toxins and virulence factors have been described on numerous occasions, including the previous edition of this textbook. However, we have come to realize that many of the biologically active proteins or toxins that were studied in mice do not have a clear role in human infection or illness.

Antigenic factors or toxins that are thought to have no significant roles in human infections or illnesses are filamentous hemagglutinin (FHA), the type III secretion system, dermonecrotic toxin (DNT), and tracheal cytotoxin (TCT). Significant biologically active proteins of *B. pertussis* are listed in Table 129.2.

Pertussis Toxin

PT is an adenosine diphosphate–ribosylating toxin that is synthesized and secreted exclusively by *B. pertussis*. It is an A-B toxin with an enzymatically active A subunit (S₁) and a B oligomer (S₂₋₅) binding portion.* PT inactivates G proteins, a process that disrupts signaling pathways and leads to histamine sensitization, enhancement of insulin

secretion in response to regulatory signals, and suppressive and stimulatory immunologic effects in animal model systems.³⁶⁷

The various effects of PT in animal model systems and in humans have been reviewed in depth by Cherry.^{113,367} In contrast to animal studies, histamine sensitization does not appear to occur in children, but PT does cause an increase in plasma insulin levels.^{113,367} PT also is responsible for leukocytosis with lymphocytosis in *B. pertussis* infections. PT is a strong adjuvant in several immunologic systems in animals, but in DTP-vaccinated persons (who have received small amounts of active toxin in the vaccine), only the enhancement of serum antibody responses to antigens of other vaccines has been demonstrated. In mouse and rat models, PT inhibits chemotaxis and migration of neutrophils, monocytes or macrophages, and lymphocytes to infection sites, and PT functions as an adhesin in the adherence of *B. pertussis* to human macrophages and ciliated respiratory epithelial cells.

PT contributes to morbidity in *B. pertussis* infections, as indicated by the severity of illness, which tends to be greater than that caused by *B. parapertussis* infection. The frequent finding of extreme leukocytosis caused by PT in neonates and young infants with fatal pertussis is noteworthy.^{122,367,414,426,427,443,602}

Adenylate Cyclase Toxin

Adenylate cyclase toxin (ACT) is an extracytoplasmic enzyme that impairs host immune cell function.^{62,113,137,266,302,367,569,590} ACT enters phagocytic cells (particularly polymorphonuclear neutrophils), where it is activated by calmodulin and catalyzes the production of supraphysiologic amounts of cyclic adenosine monophosphate from adenosine triphosphate, which intoxicates these cells.³⁶⁷

Fimbriae

Fimbriae (FIM) are protein projections on the surface of *B. pertussis*.^{367,394,401,459,477,478} They are highly immunogenic, and antibody to them and to other antigens causes agglutination of the organism. Two fimbrial antigens (i.e., FIM 2 and 3) are the main agglutinogens; LPS and PRN also are agglutinogens.^{92,477}

In the past, typing of *B. pertussis* strains was based on the agglutination patterns observed with specific antisera.^{92,169,459,477} Six specific agglutinogens were recognized, and typing was based on the presence or absence

*References 13, 14, 17, 18, 63, 113, 137, 196, 285, 325, 343, 367, 454, 453, 557.

of agglutination with each specific antiserum. Researchers later recognized that two of the agglutinogens (i.e., agglutinogens 2 and 3) are fimbrial in location (i.e., FIM 2 and FIM 3) and that agglutinogens 4, 5, and 6 are minor antigens.^{459,477} All *B. pertussis* strains contain agglutinin 1; the nature of this agglutinin is unknown.⁴⁷⁷ It could be LPS or PRN, but because the original serotyping scheme was based on heat-labile antigens, it probably was not LPS.^{53,329,543}

The fimbriae function as adhesins, but some studies suggest that they are not the primary adhesins in infection but serve to sustain the attachment established by other attachment factors.^{113,478,555,589} An in vitro study by Rodriguez and associates⁴⁷⁹ suggested that the effect of antibody to fimbriae on attachment was the result of bacterial agglutination. In the mouse model system, immunization with purified fimbriae resulted in protection against infection when challenged with *B. pertussis*.²⁹³ Data from two trials in which serologic correlates of immunity were studied indicated that antibody to fimbriae is important in protection.^{114,529}

Filamentous Hemagglutinin

FHA is a component of the cell wall of all *Bordetella* species.^{1,43,113,137,260,304,354,367,555,569} It is highly immunogenic and is the dominant attachment factor for *Bordetella* in animal model systems.^{367,495,505} However, because FHA is released in large amounts from the cell surface, its role as an adhesin must be questioned. Adhesins typically remain associated with the bacterial surface to promote maximum attachment. FHA is a component of most acellular component vaccines (i.e., DTaP and Tdap).¹⁶⁷ However, the importance of antibody to FHA and protection from disease is not clear. Some data indicated that the efficacy of vaccines containing both PT and FHA was greater than that of a vaccine containing only toxoided PT.⁵²⁷ However, the PT/FHA-containing vaccines also likely contained some PRN and FIM 2. In two studies in which serologic correlates of immunity were evaluated, FHA made no contribution to protection.^{114,529} One whole-cell component DTP vaccine in which vaccinees did not mount an antibody response to FHA was nonetheless highly efficacious.^{249,520}

Autotransporters

Pertactin

PRN is a 69-kD outer-membrane protein that plays an important role in *B. pertussis* pathogenesis by allowing the organism to resist neutrophil-mediated clearance.^{43,284,325,431,432} Antibody to PRN has a strong protective effect in aerosol-challenge studies in mice.^{87,506} In the two vaccine efficacy trials in which serologic correlates of immunity were evaluated, researchers found that antibody to PRN was most important in protection.^{114,529} In the vaccine efficacy trials conducted in the 1990s, in which mild disease and typical disease were evaluated, DTaP vaccines that contained PRN in addition to PT and FHA were significantly more effective.^{96,120,222,367} Another study revealed that anti-PRN antibodies were required for efficient phagocytosis of *B. pertussis* by host immune cells.²⁵⁹ A recent disturbing finding is the circulation of PRN-deficient mutants in the United States.^{361,447}

Other Autotransporters

In addition to PRN, 16 other autotransporters are encoded in the genome of *B. pertussis*.⁴⁴⁶ Four that have been studied in animal models are described in Table 129.2.¹ All likely play an important active role in *B. pertussis* infection by interfering with the innate immune response.

Lipopolysaccharide (Endotoxin)

The LPS of *B. pertussis* is somewhat similar to the endotoxins of other gram-negative bacteria.^{85,113,137} Its function in disease is unknown, but it may act as an adhesin.¹⁴⁹ LPS is a major cause of reactions to whole-cell pertussis vaccines.²³ LPS is a significant agglutinin. Antibody to LPS reduces colonization of *B. pertussis* in the lungs and trachea of mice after aerosol challenge.⁴⁰⁹

Polysaccharide Capsule

A *B. pertussis* capsule was identified in the prevaccine era but confirmed only recently.⁴²³ Conover and associates¹³³ and Ganguly and associates¹⁹⁹ studied the capsule and found it functions in adhesion and protects against complement-mediated killing.

EPIDEMIOLOGY

Pertussis is an extremely infectious disease with an estimated R_0 of 12 to 17. R_0 is the expected number of secondary cases produced by a typical primary case in an entirely susceptible population.^{11,116,182}

Considerable misinformation has been circulating with regard to the epidemiology of pertussis.^{55,56,106,109,105,324,480,481,586} The main reason for misinformation is failure to recognize the significant differences in the dynamics of reported pertussis compared with *B. pertussis* infections.^{101,99} Reported clinical pertussis and *B. pertussis* infection have different epidemiologies.

Reported Pertussis Cases

Rates of reported pertussis depend on surveillance programs in the reporting countries, states, or counties.⁵³⁹ For example, in Switzerland and three bordering countries (i.e., Germany, Italy, and Austria), the rates of reported pertussis for 1998 to 2002 varied by as much as 70-fold.⁶⁵ Because of the proximity of the four countries and the fact that their immunization practices were somewhat similar, the rate differences are explained by the rigorosity of the respective surveillance programs and not by any unique epidemiology by country.

Incidence

The incidence of reported pertussis and its mortality rate are affected markedly by the use of pertussis vaccine. In the prevaccine era in the United States, the average attack rate of reported pertussis was 157 cases per 100,000 people.⁸⁹

After the introduction and widespread use of pertussis vaccines, the attack rate of reported pertussis in the United States fell approximately 150-fold between 1943 and 1976. For the 7-year period from 1976 to 1982, the attack rate in the United States remained between 0.5 and 1.0 case per 100,000 people. From 1982 to 2015, the attack rate curve shifted modestly upward and reached a rate of 15.2 cases per 100,000 in 2012 (Fig. 129.1). In 2012, there were 48,277 cases of reported pertussis; this was the largest number of reported cases in the United States since 1955. Possible reasons for the resurgence of reported pertussis cases are (1) increased vaccine failures resulting from genetic changes in *B. pertussis*, (2) increased vaccine failures related to vaccines of lessened potency, (3) waning immunity, (4) greater awareness of pertussis, and (5) the availability of better laboratory tests.^{101,99,120,123,128,212,222} Among these possibilities, we think that greater awareness is the most important.

In the early 1980s, much attention was given to real and perceived reactions to DTP vaccines; later in the decade, there were many reports about the development of DTaP vaccines.* In the 1990s, the efficacy trials with DTaP vaccines were carried out and resulted in numerous publications and general overall pertussis awareness.[†]

In the current decade, there has been much attention to the general inferiority of DTaP vaccines compared with DTP vaccines.[‡]

Use of PCR is also important for diagnosis.¹²² PCR is considerably more sensitive than culture and is less likely to be adversely affected by delay in getting specimens to the laboratory. Single-serum serologic testing for pertussis is the preferred method for confirming pertussis in adults. The number of cases and the attack rate among adolescents and adults will increase when single-serum serologic diagnosis becomes routine.¹²⁴ Data indicate that waning immunity is a major factor.[§]

Fig. 129.1 shows two periods. During the first period, the increase in cases correlates mainly with increased awareness. In addition to increased awareness, the sharp peaks in 2004 to 2005 and in 2010, 2012, and 2014 are most likely due to DTaP vaccine failure, waning immunity, and the use of PCR and single-serum serology for diagnosis.

There has been considerable debate regarding the role of genetic change as a cause of vaccine failure.^{124,153,401,433,500} Over time, genetic changes in PT, PRN, and fimbriae have occurred. In 1965, Preston⁴⁵⁸

‡References 2, 35, 105, 108, 109, 305, 306, 397, 544, 600, 601, 607, 608.

§References 2, 35, 305, 306, 371, 397, 544, 600, 601, 607, 608.

FIG. 129.1 Annual pertussis incidence per 100,000 people in the United States, 1983–2014. (Data from Centers for Disease Control and Prevention. National Center for Health Statistics, Pertussis Cases by Year (1922–2014), and Summary of notifiable diseases: United States, 2014. Available at <http://www.cdc.gov/pertussis/surv-reporting/cases-by-year.html>.)

observed that the British vaccines at the time contained only agglutinin 2 (i.e., FIM 2) and that circulating *B. pertussis* strains contained agglutinin 3 (FIM 3). However, this vaccine-driven genetic change had no demonstrated adverse effect on vaccine efficacy at that time. Currently, genetic changes in *B. pertussis* include *ptx* P1 allele to *ptx* P3 allele, an increase in *fim* 3B strains in the United States, and the circulation of PRN-deficient mutants. Because whole-cell DTP vaccines contain multiple antigens, genetic changes are unlikely to lead to vaccine failure in DTP-vaccinated children. However, DTaP vaccines contain a maximum of five proteins, and genetic change would likely contribute to vaccine failure.

Studies in the Netherlands suggested that the change from *ptx* P1 to *ptx* P3 resulted in an increase in pertussis and an increase in the severity of illness.⁴⁰¹ However, this does not appear to be accurate. In Denmark, physicians have been exclusively using a PT toxoid vaccine since 1997, and there is no evidence of an increase in pertussis incidence or severity.^{282,547}

The increase in *fim* 3B strains in the United States has occurred gradually over many years, and because FIM 2 is the dominant FIM antigen, this is unlikely to contribute to vaccine failure to any great degree. In contrast, the circulation of PRN-deficient mutants is a significant problem.^{361,447} It would be a greater problem in recipients three-component vaccinees (i.e., PT, FHA, and PRN) compared with five-valent vaccinees (i.e., PT, FHA, PRN, and FIM 2/3). However, any difference in the effectiveness of the two vaccine types has not become apparent, probably because antibody to the B subunit of PT provides considerable efficacy against typical pertussis. To show a difference in effectiveness, a study involving mild illness and typical pertussis in DTaP vaccine failures would need to be carried out. Vaccine failure is discussed later in this chapter.

Pertussis epidemics in the prevaccine era occurred at 2- to 5-year intervals (average, 3.2 years in the United States), and these cycles have continued in the vaccine era. As reported by Fine and Clarkson,^{184,185} this continuity indicates that although immunization has controlled the disease, it has not reduced transmission of the organism in the population.^{89,94,97}

In the prevaccine era, the following percentages of cases by age were reported in Massachusetts: younger than 1 year, 7.5%; 1 to 4 years, 41.1%; 5 to 9 years, 46.0%; 10 to 14 years, 4.1%; and 15 years and older, 0.9%.⁴⁹ Associated with the marked reduction in reported cases of pertussis in the United States resulting from widespread pediatric

immunization, a major shift occurred in the percentages by age category in the United States.⁴⁹ During the period from 1978 to 1981, the age distribution was as follows: younger than 1 year, 53.5%; 1 to 4 years, 26.5%; 5 to 9 years, 8.2%; 10 to 14 years, 5.4%; and 15 years or older, 6.5%. In contrast, U.S. data for 2010 revealed the following pattern: younger than 1 year, 15%; 1 to 6 years, 22%; 7 to 10 years, 18%; 10 to 19 years, 20%; and 20 years or older, 25%. Today, pertussis among adolescents and adults is an important source of *B. pertussis* infection for unimmunized or partially immunized children.* The disease in adolescents and adults usually is not recognized as pertussis, although the cough frequently is paroxysmal and illness may persist for weeks.^{97,155,358,457,503}

In a study of university students, members of our group found that about 13% of students with an illness involving cough for 6 or more days had *B. pertussis* infections, none of which had been diagnosed correctly clinically.³⁹³ The study findings led to the suggestion that *B. pertussis* infections are endemic among adults and are responsible for cyclic outbreaks among susceptible children. Other studies in the United States, Germany, and elsewhere support this hypothesis.^{45,97,99,101,150,156,401,503,604,616}

Morbidity and Mortality

During the first 30 years of the 20th century, pertussis was an important cause of death in the United States.³¹⁹ The number of deaths from pertussis between 1926 and 1930 was 36,013,²⁰⁸ mostly children younger than 1 year of age. The pertussis death rate curve in the United States declined throughout the 20th century. Among infants, the mortality rate decreased approximately fivefold between 1900 and 1944. During the next 35 years, it declined more than 85-fold.^{406,407} Today, most of the deaths caused by pertussis affect unimmunized infants younger than 4 months of age.^{221,225,367,414,572,615,622} Currently in the United States, 10 to 20 deaths are reported each year.^{74,79,76,221,572,615}

Deaths caused by pertussis frequently are misdiagnosed as deaths from other respiratory tract infectious illnesses.^{89,253,425} For example, in England and Wales during the epidemic from 1977 to 1979 and at the beginning of the epidemic in 1982, 32 deaths were reported to be caused by pertussis.⁸⁹ However, when the excess deaths from other respiratory tract infectious illnesses were examined, approximately 362 additional deaths appeared to be caused by pertussis. Additional pertussis deaths were reported as SIDS.⁴²⁵

*References 46, 82, 97, 101, 99, 111, 317, 339, 340, 405, 419, 560, 592.

The morbidity caused by pertussis in recent years can be gleaned from numerous reports. The numbers of pertussis-related hospitalizations, complications, and deaths in the United States during 1990 to 1996 were reviewed in 1999 by Güris and colleagues.²²¹ Of the 31,837 cases analyzed, 31.7% of patients were hospitalized, 9.5% had pneumonia, 1.4% had seizures, 0.2% had encephalopathy, and 0.2% died. The most severe morbidity rate was for infants younger than 6 months of age. Of this group, 72.2% were hospitalized, 17.3% had pneumonia, 2.1% had seizures, 0.5% had encephalopathy, and 0.5% died. During the period from 2000 to 2004, 12,174 cases among infants were reported.⁸² Of this group, 62.8% were hospitalized, 55.8% had apnea, 12.7% had pneumonia, 1.5% had seizures, and 0.8% died.

In adolescents with reported pertussis, 0% to 2% are hospitalized, and 2% have pneumonia.⁸¹ A review of data from seven studies of adult pertussis reported the following findings: hospitalization, 3% to 12%; seizures, 0% to 0.6%; rib fracture, 0% to 4%; and pneumonia, 0.6% to 8%.⁸²

A pertussis surveillance system was introduced in conjunction with a large pertussis vaccine efficacy trial in several regions of Germany in 1990. The initial results of this ongoing surveillance study were published in 1993.²⁴⁷ Of 601 culture-proven cases, 12.3% occurred among infants, and 86.2% occurred among children younger than 6 years of age. Serious complications were reported in 22 of 275 patients with follow-up and included pneumonia in 5.5%, apnea in 2.2%, and cardiorespiratory failure in 0.4%.

In a follow-up report of the same study, 1 of 185 culture-confirmed cases among infants was fatal.²⁵¹ In another German study from 1993 to 1996, Herzig and associates²⁶² reported 116 hospitalized pertussis patients with the following complications: pneumonia in 81%, apnea requiring assisted ventilation in 15%, seizures in 14%, encephalopathy in 5%, and death of 2%. In Canada from 1991 to 1997, Halperin and colleagues²³⁵ analyzed the complications of pertussis in 1082 hospitalized children younger than 2 years of age and found that 9.4% had pneumonia, 3% had atelectasis, 2.3% had seizures, 0.59% had encephalopathy, 0.8% had inguinal or umbilical hernias, 1.3% had more than a 5% weight loss, and 0.9% died.

Since 2010, several studies in California have examined risk factors for death in young infants.^{413,426,602} These studies are discussed in later sections.

Season, Geography, Race, Ethnicity, and Sex

Pertussis occurs throughout the world, but data from large parts of Asia and Africa are less detailed than data from the United States, Canada, Australia, and Europe.^{106,109,113,538} Historically, epidemic pertussis had no seasonal pattern.⁸⁹ However, in the current vaccine era in North America, pertussis usually occurs in the summer and fall.^{123,177,207,221,367,419}

The incidence of pertussis is usually greater among female than male patients.^{89,177,207,221,584} In 2004, 25,827 cases were reported in the United States; 11,199 (45%) of these patients were male, and 13,879 (55%) were female; sex was not identified in 749 cases.⁷⁸ In 2010, 55% of the reported cases occurred in females. In a large study in Germany, 1263 (50.7%) of the 2493 patients were female.²⁵¹

Reported pertussis rates were higher among American Indians and Alaska Natives and whites than among Asians and Pacific Islanders and blacks in 2010.⁷⁴ Attack rates for infants are higher among Hispanics than non-Hispanics.

Transmission

Transmission is thought to occur by droplets from a coughing or sneezing patient that reach the upper respiratory tract of a susceptible person. Indirect spread also may occur. A symptomatic patient could contaminate the environment with respiratory secretions; the hands of another person could make contact with the secretions and then inoculate the respiratory tract.¹¹³ Attack rates among susceptible household contacts range from 70% to 100%.^{89,113} Antibody studies indicate that asymptomatic infections also occur among contacts.^{150,346,347} These asymptomatic infections are likely to be short lived and probably are not important with regard to contagion.

Transmissibility is greatest early in the illness, occurring during the catarrhal and early paroxysmal phases. Young children with primary

infections shed more bacteria for a longer period than do older children, adolescents, and adults who have had a previous infection (recognized or not recognized) or previous immunization.

Bordetella pertussis Infection

The current cyclic pattern of reported pertussis is similar to what it was in the prevaccine era³⁶⁷ but is different from that seen with other diseases that have been brought under control by universal immunization.^{97,101,99,393} For example, as measles was brought under control, the interepidemic cycle lengthened because circulation of the measles virus in the population had been reduced. In contrast, immunization controlled pertussis but did not decrease the circulation of *B. pertussis*.^{185,186} In the 1970s, Nelson⁴¹⁹ observed that the source of *B. pertussis* infection in hospitalized infants most often was an adult. This observation led many investigators to suspect that *B. pertussis* infections were endemic among adolescents and adults.^{97,393} Sporadic infection in the adolescent and adult reservoir is the major source of *B. pertussis* infections in nonimmune children.^{109,511,46,141,142,314,367,566,592} The cyclic pattern occurs because it takes a few years for a significant number of susceptible members of the population to develop and for an outbreak to result from the sustained transmission.

Understanding of the importance of adolescent and adult *B. pertussis* infections resulted from the ability to diagnose infection serologically by measuring immunoglobulin (Ig) G and IgA antibodies to PT by enzyme-linked immunosorbent assay (ELISA).^{99,101,124,367,393,462} During the past 30 years, numerous studies of adolescent and adult populations have contributed to the understanding of *B. pertussis* epidemiology.

Studies of prolonged illnesses with cough in adolescents and adults suggest that about 13% of the illnesses are caused by *B. pertussis* infection.* Many studies have looked at overall infection rates by determining significant IgG or IgA titer rises in response to PT in persons who have two or more serum samples collected over extended periods.^{99,101,140,156,267,367,483,579} These studies suggest that between 1.0% and 6.6% of adolescents and adults have a *B. pertussis* infection each year. A large study in the Netherlands that used a combination of serologic surveys estimated an incidence of infection of 6.6% per year for persons between the ages of 3 and 79 years.¹⁵⁴ The incidence among children 3 to 4 years of age was 3.3%. It then increased gradually to a peak of 10.8% among those 20 to 24 years of age. Other age-specific incidences were 6.5% for persons 25 to 55 years old and 4.0% for those older than 55 years of age.

The rates of illnesses with cough caused by *B. pertussis* were determined in two prospective, specific population-based studies.^{532,578} In the first study, the rate was 500 cases per 100,000 people (0.5%), and in the second, it was 370 cases per 100,000 people (0.37%). These figures underestimated the rates because of observer bias.¹¹⁸ In both studies, the study physicians or nurses were supposed to document all patients with cough illnesses of 7 days or longer who were not improving. If the physicians or nurses did not follow the protocol but made decisions based on their opinions, many mild cases would be missed, and there is evidence of this error in both studies. The retrospective serologic analysis of a respiratory disease study of adults older than 65 years of age suggested a rate as high as 1.5%.²⁶⁷ This high value assumes that all respiratory illnesses with cough during the 4-month periods of seroconversion were the result of *B. pertussis* infection.

With increased clinical surveillance and more complete use of the laboratory (i.e., PCR and serologic study), and with the diagnosis of mild cases in children, adolescents, and adults of all ages, the current cyclic pattern of reported pertussis for the most part will disappear. The pattern of reported pertussis has already lost some of its predictable regularity in some European countries with rigorous surveillance systems in place.

PATHOLOGY

Data on the pathology of *B. pertussis* infections have been determined mainly by postmortem study of fatal cases.^{89,113,121,126,319,338,355,443,512} However,

*References 45, 99, 101, 201, 291, 367, 393, 422, 485, 503, 532, 571, 604, 616.

some information about uncomplicated pertussis can be gleaned from experiments done more than 80 years ago using rhesus and ringtail monkeys.^{319,496} Pure cultures of *B. pertussis* were obtained from between the cilia of the smaller bronchi and bronchioli. Endobronchitis and peribronchitis were identified, and the bronchi contained leukocytes, mucus, and debris.

In a study of autopsy material from 15 infants (≤ 4 months of age), the consistent histopathologic features were necrotizing bronchiolitis and pneumonia, intraalveolar hemorrhage and fibrinous edema, and abundant intraalveolar macrophages.⁴⁴³ Angiolymphatic aggregates of mixed leukocytes in the intralobular septa and pleurae were seen in 86% of the specimens. Intact *Bordetella* organisms were found in cilia of the trachea, bronchi, and bronchioles and within airways and alveoli. They also were seen intracellularly in alveolar macrophages and respiratory epithelium. Despite the fact that all patients had severe pneumonia, the ciliated respiratory epithelial cells appeared relatively normal. More than 100 years ago, Mallory and Horner³⁵⁵ also found that the ciliated epithelial cells in the trachea, bronchi, and bronchioles were relatively normal. Six of the 15 deaths studied had evidence of coinfections with one or more other agents (i.e., cytomegalovirus, 1 child; RSV, 2 children; *Streptococcus pneumoniae*, 2 children; *Streptococcus pyogenes*, 2 patients; *Moraxella catarrhalis*, 1 child; and viridans streptococci, 1 child). It is likely that many of the pathologic findings described earlier resulted from concomitant and secondary viral or bacterial infections and not from the *B. pertussis* infection.¹²¹

Pathologic changes in the brain and liver have been described. Microscopic or gross cerebral hemorrhage may be seen, and cortical atrophy has been observed. These changes most likely are the result of anoxic brain damage. In some studies of pertussis encephalopathy, findings suggested meningoencephalitis, with perivascular cuffs of lymphocytes in cerebral gray matter and pleocytosis.⁶¹¹ However, the studies in which inflammation was demonstrated were performed before modern virologic techniques became available. The neurologic findings in these instances probably were caused by interactions with neurotropic viruses or other infectious agents and were not the result of *B. pertussis* infection.¹¹³ Fatty infiltration of the liver has been recognized in patients with pertussis encephalopathy.

PATHOGENESIS AND IMMUNITY

After a patient is exposed to an infectious agent, the pathogenesis of infection usually depends on four important steps: attachment, evasion of host defenses, local damage, and systemic disease.^{113,137,204,264,367,409,411,416,459,589} However, illness due to *B. pertussis* infection is unique because there is no systemic disease and, except in young infants, there is no local damage.^{109,105,121} The biologically active antigenic components of *B. pertussis* listed in Table 129.2 have various roles in pathogenesis. During the past 2 decades, hundreds of research publications have explored the effects of various *B. pertussis* proteins in animal model systems. These studies have revealed a large amount of information, but what is missing for the most part is the degree of correlation with pathogenesis in human infections.*

Infection is initiated in the respiratory tract by the attachment of *B. pertussis* organisms to the cilia of ciliated epithelial cells.⁵⁸⁹ Adhesins (e.g., PT, FIM, LPS) facilitate attachment.⁴¹¹ Because of the redundancy of protein adhesins, determining the importance of the individual proteins and ascertaining a primary adhesin or adhesins have been difficult.³⁶⁷ For the attachment proteins, data about human infection are available only for FIMs. In the two trials that looked at serologic correlates of immunity, researchers found that antibody to fimbriae was important.^{111,529} Antibodies to fimbriae provided protection against colonization with *B. pertussis* in the murine respiratory tract.⁵⁹⁶

In many publications, PRN and other autotransporters are described as adhesins, which is mostly incorrect. Although antibody to PRN is associated with lack of attachment, PRN and other autotransporters have other specific biologic activities in infection.^{29,259,359,360,430,438,597} The two household contact studies of serologic correlates of protection found

that antibody to PRN was most important in preventing pertussis.^{114,529} PRN and all of the other autotransporters that have been studied adversely affect the innate immune response.

ACT and PT adversely affect immune cell function and therefore allow infection to continue after initiation.^{13,14,62,113,266,411,569} PT prevents migration of lymphocytes and macrophages to areas of infection and adversely affects phagocytosis and intracellular killing. ACT enters phagocytic cells and catalyzes excessive production of cyclic adenosine monophosphate, which intoxicates neutrophils and decreases phagocytosis.

TCT and DNT have been suggested to be contributors to local tissue damage in the respiratory tract.^{113,204,416} However, there are no data indicating tissue damage in human infections due to these two proteins.

Pertussis is a unique illness in that fever does not occur, and it has only one manifestation of systemic disease in uncomplicated infection: leukocytosis with lymphocytosis caused by PT.^{113,256,281} T and B lymphocytes increase to a similar extent in the circulation.⁴¹ Unlike the situation in *B. pertussis* infection, leukocytosis with lymphocytosis is not a characteristic of *B. parapertussis* infection because the organism does not liberate PT. Clinical experience and recent studies indicate that PT is the major causative factor in deaths in young infants.^{414,443,602,622}

PT inhibits G proteins, causing leukocytosis with lymphocytosis. It has been suggested that the extreme leukocytosis results in obstruction in small pulmonary vessels, which leads to severe pulmonary hypertension.⁴⁴³ However, it is possible that the inhibition of G proteins in other cells in the lung or heart is the cause of death.^{414,622} An important systemic complication of pertussis is encephalopathy, for which the mechanism is unknown. The most likely explanation is anoxia associated with coughing paroxysms.

It has been suggested that pertussis is a toxin-mediated disease caused by PT.^{454,453} Although some researchers continue to entertain this idea,^{473,474} little evidence supports it. PT is a fascinating protein with activities in experimental animals such as histamine sensitization, promotion of lymphocytosis, effects on glucose metabolism, and induction of adjuvant and mitogenic activity.^{79,145,284,326} However, in human infections, the main effects that appear to be caused by PT are leukocytosis with lymphocytosis and mild, compensated hyperinsulinemia. PT has been suggested as the cause of the prolonged cough in pertussis, but this hypothesis should be refuted because persistent cough is a major manifestation of *B. bronchiseptica* infection in dogs and of *B. parapertussis* and *B. holmesii* infection in humans and because none of these organisms liberates PT.^{256,367,432}

The hallmark of *B. pertussis* illness is paroxysmal cough, and the cause (i.e., cough toxin) is unknown.^{105,109,121} The paroxysmal cough is unique because of its long duration. Because there is memory of the cough, it may return when people have subsequent respiratory tract viral infections. Hewitt and Canning²⁶³ suggested that bradykinin plays a role in the initiation of the cough. During *B. pertussis* infection, bradykinin production is increased and has a prolonged half-life in the airways, and responsiveness to bradykinin receptor activation is increased. Bradykinin activates sensory nerves implicated in cough. What is not known is the *Bordetella* antigen (i.e., cough toxin) that stimulates the unique coughing process.

Cell-mediated immune responses (i.e., T-cell response) in *B. pertussis* infection and after immunization were observed more than 2 decades ago and in one of the vaccine efficacy trials of the 1990s.* In a murine model, Mills and colleagues found that infection or DTP immunization resulted in a helper T-cell type 1 (Th1) response, whereas vaccination with a DTaP vaccine resulted in a Th1/Th2 response. Because the antibody responses with the DTaP vaccines were good, the T-cell response findings were ignored by most people involved with pertussis vaccine studies in the 1990s.

However, recent findings of a diminished duration of efficacy in DTaP vaccine recipients compared with DTP vaccine recipients have led to renewed interest in cellular immunity after infection and vaccination. Studies using the baboon pertussis model have confirmed and expanded the findings of Mills and associates.^{390,391,490} Warfel and Merkel⁵⁸⁰

and Warfel and colleagues⁵⁸¹ found that infection and DTP vaccination induced a Th17 and Th1 immune memory response, whereas the response to DTap was a Th1/Th2 response. The Th17 and Th1 response prevents infection and disease, and it gives longer protection than a Th1/Th2 response.

Various antibodies develop after exposure of the human host to infection with *B. pertussis*. The development of agglutinins, hemagglutination-inhibiting antibodies, and bactericidal antibodies has been described.⁸⁹ ELISA techniques have demonstrated class-specific antibodies (i.e., IgA, IgE, IgG, and IgM) to many of the specific proteins of *B. pertussis*.^{243,356,441} The antibodies develop after infection and, with the exception of IgA antibodies, after immunization. Neutralizing antibody to PT develops after infection and immunization.^{231,441} Specific IgA antibodies to PT and FHA also can be demonstrated in nasopharyngeal secretions and saliva.^{210,619}

B. pertussis infection and immunization with whole-cell or acellular pertussis vaccines elicit protection to various degrees and durations against pertussis. The prevailing opinion in the past century was that immunity acquired from having *B. pertussis* infection was lifelong, whereas vaccine-induced immunity was relatively short. Although the latter is true,¹⁸⁵ studies performed by members of our research group suggest that the former opinion regarding infection-induced immunity is wrong.^{95,98,112,367,503,568} Proceeding from the knowledge that IgA antibodies to pertussis antigens (i.e., PT, FHA, and PRN) result from infection and not from primary vaccination, our group studied the prevalence of these antibodies in the sera of young German and American men of similar ages.¹¹² In Germany, routine childhood immunization was not carried out during the 1970s and 1980s, and pertussis was epidemic. To our surprise, the rate and mean values of IgA antibodies in the two populations were similar, suggesting that adult infection rates were similar. However, levels of IgG antibody to PT, FHA, PRN, and FIM 2 were significantly higher in young American men than in German men of similar ages. In another study in Germany, we found that *Bordetella* infections were common occurrences in adults, often in persons with a known history of childhood pertussis.⁵⁰³

In our studies of cases of pertussis in adults in the United States and Germany, we observed that the Germans (primed by past infection) tended to have more typical pertussis than the Americans (primed by DTP vaccination). The nature of immunity in pertussis is unknown. The consensus is that serum antibodies greater than some unknown concentration to one or more of the pertussis antigens are responsible for protection.¹⁵⁰ Antibodies to PT, FHA, and PRN are protective in animal model systems,^{43,139,325,495,506} but no serologic correlates of immunity were established until the 1990s, although several large vaccine trials were carried out in the late 1980s and early 1990s.^{3,212,222,332,509,520,553}

In a nested household contact study, our group was able to evaluate the roles of IgG antibodies to PT, FHA, PRN, and FIM 2 by determining preexposure imputed values in children at the time of household exposure to *B. pertussis* infection by using a classification tree and logistic regression methods.¹¹⁴ The imputed geometric mean antibody values to PT, PRN, and FIM 2 were higher for noncases than for cases. In the classification tree analysis, however, only antibodies against PRN contributed significantly to protection. Subjects with an imputed PRN value of less than 7 ELISA units (EU) per milliliter had a 67% likelihood of infection. Logistic regression analysis found that PRN values of 8 EU/mL or more were associated with protection from illness after household exposure. In accordance with our findings, data from a Swedish study, which had greater power, indicated that antibody values of 5 EU/mL or more to PRN and FIM 2/3 correlated with protection.⁵²⁹ The data from these two studies suggest that antibody to PRN and FIM are most important in protection. However, what is difficult to understand is why some children get pertussis despite large amounts of antibody to PRN or FIM or both.^{117,552} Data from a study by Weiss and associates⁵⁹¹ suggested that high antibody values to PT might block the protective effect of antibody to the more important antigens.

Immunity developed after *B. pertussis* infection or vaccination with a whole-cell pertussis vaccine does not protect against illness caused by *B. parapertussis*, and infection with *B. parapertussis* does not induce protection against disease caused by *B. pertussis*.^{320,542} However, the results of our vaccine efficacy trial in Germany provided evidence that the

acellular, multicomponent pertussis vaccine, which contained a large amount of FHA, offered some protection against *B. parapertussis* infections, whereas the whole-cell vaccine, which contained minimal amounts of FHA, did not.²⁵⁴ Although *B. pertussis* infection is a localized infection involving ciliated cells of the respiratory tract, bacteremia has occurred in immunocompromised adults.^{77,290,554}

CLINICAL MANIFESTATIONS

The clinical manifestations of *B. pertussis* infection have considerable variation that depends on age, previous immunization or infection, the presence of passively acquired antibody, and other factors such as the degree of exposure, host genetic and acquired factors, and the genotype of the organism. The incubation period for pertussis is 6 to 20 days; in most cases, onset occurs 7 to 10 days after exposure. However, after household exposure, 22% of secondary cases had an onset of more than 4 weeks after the onset of illness in the primary case.²⁴⁹

Classic Illness

Classic illness occurs as a primary infection in unimmunized children between the ages of 1 and 10 years.^{98,113,124,208,439} The illness usually lasts 6 to 12 weeks and has three stages: catarrhal, paroxysmal, and convalescent. The initial illness is characterized by rhinorrhea, lacrimation, and mild cough suggesting a common cold. Body temperature usually is normal. The severity of the cough gradually increases over 1 to 2 weeks, but pertussis usually is not suspected until the cough becomes paroxysmal.

After the catarrhal period, the coughing increases in severity and number of attacks. Repetitive series of 5 to 10 or more forceful coughs can occur during a single expiration. The paroxysms are followed by a sudden, massive inspiratory effort, and a characteristic whoop may occur as air is forcefully inhaled through a narrowed glottis. Cyanosis, bulging eyes, protrusion of the tongue, salivation, lacrimation, and distention of neck veins occur during paroxysms. Several paroxysmal coughing episodes with their associated massive inspiratory effort may occur sequentially. Purulent sputum is not produced. Posttussive vomiting is a common occurrence. Paroxysms may strike several times per hour, and they occur during both day and night.

The paroxysmal episodes are exhausting, and patients frequently appear dazed and apathetic. Weight loss may occur as a result of vomiting, and eating and drinking may be resisted because they trigger attacks. Attacks also may be triggered by yawning, sneezing, or physical exertion. Between attacks, the patient may appear normal and usually is in no distress.

Common and important complications of classic pertussis include pneumonia, otitis media, seizures, and encephalopathy. Pneumonia in all but young infants is caused by secondary bacterial or viral invaders. Atelectasis may develop as a result of the mucus plugs. The forcefulness of the paroxysms can rupture alveoli and produce interstitial or subcutaneous emphysema.

Otitis media is a common occurrence and frequently is caused by *S. pneumoniae*. Pertussis also has been associated with activation of latent tuberculosis. Convulsions and coma may be observed. Findings may reflect cerebral hypoxia related to asphyxia. Rarely, subarachnoid and intraventricular hemorrhage may occur. Tetanic seizures may be associated with the severe alkalosis that results from the loss of gastric contents caused by persistent vomiting.

Other complications include ulcer of the frenulum of the tongue, epistaxis, melena, subconjunctival hemorrhage, subdural hematoma, spinal epidural hematoma, rupture of the diaphragm, umbilical hernia, inguinal hernia, rectal prolapse, dehydration, meningoencephalitis, the syndrome of inappropriate secretion of antidiuretic hormone, apnea, rib fracture, and nutritional disturbances.^{66,98,287,366,457,514,585}

The convalescent stage, which usually lasts 1 to 2 weeks, is characterized by a decreasing frequency and severity of coughing episodes, whooping, and vomiting. However, some patients continue to have pertussis-like coughing spells for several months. Most patients with classic pertussis caused by primary infection have leukocytosis associated with lymphocytosis. Fever, pharyngitis, and wheezing are not usual manifestations in pertussis, and a search for a secondary cause should

be undertaken when these findings occur. Except for the observation of typical paroxysmal cough and detection of the complications previously described, physical examination of patients with pertussis usually is unrewarding. Diffuse rhonchi may be elicited on auscultation.

Infection with *B. parapertussis* causes an illness that is similar to that caused by *B. pertussis*. However, it is usually less severe and has a shortened duration.^{255,333,364}

Mild Illness and Asymptomatic Infection

Mild, nonclassic illness is common in *B. pertussis* infection.^{150,247,251,498} It occurs in previously vaccinated individuals and as a primary infection in unvaccinated children. In a study in which physicians were encouraged to send nasopharyngeal specimens from ill children with cough, regardless of whether the illness was typical of pertussis, to our laboratory, 247 culture-positive cases were identified. Of these patients, 47% had a total duration of cough of 28 days or less. For 26%, the duration of cough was less than 3 weeks. Most of these patients were unvaccinated children. In a similar 6-year study involving 2592 culture-positive, previously unvaccinated children, 38% had a duration of cough of 28 days or less, and for 17%, it was 21 days or less.²⁵¹ In a study in which both culture and PCR were used for establishing the diagnosis of *B. pertussis* infection, many mild cases were found to be PCR positive and culture negative.⁴⁹⁸ Of these, only 68% had a cough lasting 4 weeks or longer, and only 57% and 32% had paroxysmal cough and whoop, respectively.

In studies of household contacts, asymptomatic infections in family members are common occurrences.^{150,346,347} Deen and associates¹⁵⁰ found that 52 (46%) of 114 household contacts who remained well had laboratory evidence of *B. pertussis* infection. In another study, 21 of 399 healthy infants who were control subjects had PCR-positive nasopharyngeal samples.²⁵⁰

Infants

Pertussis in infancy is a unique experience.^{367,414,602} Its spectrum of clinical manifestations varies by age, immunization, and the magnitude of transplacentally acquired antibody.* Most deaths resulting from *B. pertussis* infection affect neonates and occur during early infancy, and morbidity is most severe in infants.[†] From 1997 through 2000, 8276 cases of pertussis were reported for infants in the United States.⁷⁶ Of this group, 59% of the infants were hospitalized, 11% had pneumonia, 1% had seizures, 0.2% had encephalopathy, and 0.7% died. Eighty-seven percent of these patients were children younger than 6 months of age.

B. pertussis infection in neonates is particularly severe, with a death rate of 1% to 3%.^{36,127,221,253,255,274,336,373} Clinical characteristics of pertussis in early infancy are presented in Box 129.1. A common initial finding is apnea with or without typical coughing. Seizures associated with apnea caused by hypoxia occur frequently. Severe pulmonary hypertension is a relatively common problem in pertussis in the first 4 months of life.^{147,160,209,218,227,443,449,517,598} The severity of disease and the risk for death correlate directly with high white blood cell (WBC) counts, particularly the number of lymphocytes.^{36,127,147,218,253,373,383,443,449} WBC counts in the range of 30,000 to more than 100,000 cells/mm³ are common findings.

Two California Department of Public Health studies have provided useful information about risk factors for pulmonary hypertension and death.^{414,602,622} The first study involved 31 infants 90 days of age or younger with pertussis who were admitted to a pediatric intensive care unit in Southern California. Infants with pulmonary hypertension or who died had higher WBC counts, had more rapid pulse and respiratory rates, and were more likely to have early onset pneumonia than those who did not have pulmonary hypertension or who died.

In a second Californian study in which 53 fatal pertussis cases from 1998 to 2010 were matched with 183 nonfatal pertussis cases of hospitalized patients older than 120 days of age, the findings in the previous California study were confirmed.^{413,602} Additional risk factors for death

BOX 129.1 Clinical Features of Pertussis in Young Infants

- Infant looks deceptively well initially; coryza, sneezing, clearing throat, no fever, mild cough
- Paroxysmal stage: gagging, gasping, eye bulging, bradycardia (tachycardia in severe illness), cyanosis, vomiting
- Leukocytosis with lymphocytosis
- Apneic episodes
- Seizures
- Respiratory distress
- Pneumonia and pulmonary hypertension
- Shock or hypotension with renal failure and/or other organ failure
- Death associated with pulmonary hypertension and pneumonia
- Adenovirus or respiratory syncytial virus coinfection confuses picture

were lower birth weight, lower gestational age, and onset of symptoms at an earlier age. Factors associated with survival were paroxysmal cough and the receipt of DTaP vaccine. Treatment characteristics associated with death included the recipient of steroids or nitric oxide and the use of intubation, exchange blood transfusion, and extracorporeal membrane oxygenation (ECMO). The use of macrolide antibiotics correlated with survival.

In a stepwise logistic regression model, indicators of death were low birth weight, extremely high WBC count, and pulmonary hypertension. When treatment characteristics were analyzed in the multivariate, stepwise logistic regression model, only intubation and nitric oxide use were related to death. The association of death with exchange blood transfusion is misleading. All of the patients who died were in cardiovascular shock, and many also had organ failure before the procedure. In another California study, of 10 infants who received exchange blood transfusion, five died and five survived.⁴²⁶ All five infants who died were in shock, and four of five had organ failure before the procedure was attempted. In the five survivors, the procedure was done before shock or organ failure occurred.

Coinfection with respiratory viruses (e.g., RSV, adenovirus, influenza viruses) and respiratory bacterial pathogens (e.g., *S. pneumoniae*, *Haemophilus influenzae*) is relatively frequent.^{16,36,136,142,144,245,313,328,396,443,512}

B. pertussis infection has been associated with SIDS, but a cause-and-effect relationship is unlikely.^{250,255,336,425} In a study in England, Nichol and Gardner⁴²⁵ found that many deaths attributed to SIDS were instead related to *B. pertussis* infection. Using PCR, we found *B. pertussis* DNA in nasopharyngeal specimens from 9 (18%) of 51 infants who had sudden, unexpected deaths.²⁵⁵ In a subsequent study, we collected specimens for PCR from 254 infants who had sudden, unexplained deaths and from 441 healthy matched controls.²⁵⁰ The rate of PCR-positive results for the sudden death cases was 5.1%; it was 5.3% for the controls. In a careful follow-up histopathologic study with unique immunohistochemical staining of specimens from a subset of these fatal cases, we found no evidence of specific *B. pertussis* pulmonary infection or pathologic features.¹²²

The source of infection in infants usually is a family member.^{30,46,142,150,173,314,591} In a study of 616 infant cases, the source was identified for 43%.⁴⁶ A family member was the source for 75% of cases, and the mother was the most common source (32%). Of the sources, 56% were adults, and 20% were 10 to 19 years of age. In contrast to previous studies, a Centers for Disease Control and Prevention (CDC) study found that siblings were the most common source of transmission to infants.⁵¹¹

Adults

There has been increased awareness of adult pertussis since the 1970s.* Unrecognized adult pertussis cases often are the source from which

infants and children become infected.^{36,46,97,127,253,373,419,531,592} All adults were previously exposed to *B. pertussis* antigens by immunization or infection, or both,^{112,150,156,367} and exposure tends to modify their illness. In a US study, several cough characteristics were observed in 31 university students with laboratory evidence of *Bordetella* infection. The median duration was 21 days before initial evaluation, 94% had one or more coughing episodes per hour, and 90% of the coughs had a staccato or paroxysmal quality.³⁹³ Despite these findings, pertussis was not suspected in any of the students. Clinical diagnoses by the primary care providers included upper respiratory tract infection (39%), bronchitis (48%), and other diagnoses (16%). Although specific records were not available, most of the students probably were vaccinated as children and almost certainly had previous, unrecognized infections.^{112,150}

In contrast to the US findings, German adults were found to be more likely to have typical pertussis, even though the epidemiologic data suggested that all had a previous infection and 26% of 64 patients with laboratory evidence of infection recalled having had pertussis during childhood.^{112,503} Rates of clinical manifestations in the 64 laboratory-confirmed cases were paroxysms (70%), whoop (38%), posttussive phlegm (66%), and posttussive vomiting (17%). The clinical diagnosis for 39% was definite or probable pertussis; only 14% were thought not to have pertussis. The clinical diagnosis was not made by primary care physicians but by a small team of specially trained central investigators who were alert to the possibility of pertussis.

Similar findings were reported in a German household contact study: 80% of 79 adults with laboratory-confirmed *B. pertussis* infection coughed for 3 or more weeks, and 63% had spasmodic cough for 3 or more weeks.⁴⁵⁷ In 53% of patients, coughing was followed by choking or vomiting. However, only 8% of the adults in this study had whoops. Complications included pneumonia, rib fracture, inguinal hernia, and severe weight loss. Unique sweating episodes are reported in approximately 5% of adults, and fainting can be associated with coughing.^{103,165,480}

DIFFERENTIAL DIAGNOSIS

In typical pertussis, the clinical diagnosis should be apparent based on the paroxysmal cough with posttussive vomiting and whooping and a lack of significant fever. However, the cause of the illness can be *B. pertussis*, *B. parapertussis*, *B. holmesii*, and perhaps *B. bronchiseptica*. A history of contact with a known case helps to establish the diagnosis for a patient with mild or atypical illness. Leukocytosis with lymphocytosis in a child with a cough or apnea in an infant is a strong indication that the illness is caused by *B. pertussis* rather than another *Bordetella* spp. In a matched-control comparison, none of 11 children with culture-proven *B. parapertussis* infection versus 7 (32%) of 22 with *B. pertussis* infection had lymphocytosis of 10,000 cells/mm³ or more.²⁵⁶ Lymphocytosis of 10,000 cells/mm³ or more is observed in few other illnesses that manifest with a cough.

Many other infectious agents cause illnesses with prolonged and repetitive cough that can be confused with *B. pertussis* infections.³⁶⁷ In particular, *M. pneumoniae*, *C. pneumoniae*, adenoviruses, bocavirus, and other respiratory viruses can cause a prolonged cough.^{19,26,89,113,130,132,145,228,420,606} Coughing episodes also may be seen in children with asthma, bronchiolitis, bacterial pneumonia, cystic fibrosis, *Coccidioides immitis* infection, and other fungal pulmonary infections and tuberculosis. Another problem is the cough associated with sinusitis, which can be confused with *B. pertussis* infection. The cough associated with gastroesophageal reflux also can be confused with pertussis, as can cough associated with a foreign body in the airway.

DIAGNOSIS

The diagnosis of pertussis relies on the combination of clinical and laboratory findings. A laboratory diagnosis of pertussis caused by *B. pertussis* or other *Bordetella* spp. can be made by culturing the organisms on appropriate media, by PCR, and by demonstrating a specific antibody titer rise or a high single-serum antibody titer. *Bordetella* spp. can be recovered from nasopharyngeal specimens, with the highest rate of isolation occurring within the first 3 weeks of cough.^{247,531} Specimens

for culture can be collected by swabbing the nasopharynx, by nasopharyngeal washing, or by nasopharyngeal aspiration.^{113,229} Nasopharyngeal aspiration typically gives the highest yield of positive cultures, and nasopharyngeal wash is the least sensitive.

B. pertussis and *B. parapertussis* are recovered most easily by direct plating of the specimen from the patient onto selective media.^{113,115,271,345} Specific swabs (i.e., calcium alginate or Dacron) and media (i.e., Regan-Lowe or Bordet-Gengou agar and modified Stainer-Scholte broth) are required, and laboratory personnel should be experienced in isolating the organisms. If cultures cannot be inoculated directly, the use of Regan-Lowe transport medium is recommended. In classic disease, the culture is positive in approximately 80% of cases if the specimen is obtained within 2 weeks of the onset of cough and antibiotics have not been administered previously.^{248,441}

Direct fluorescent antibody testing has been used for the diagnosis of pertussis caused by *B. pertussis* or *B. parapertussis* during the past 50 years.^{367,410,521} It is rapid and inexpensive, but it lacks sensitivity and specificity; it does not employ amplification for sensitivity, and it lacks specificity because of cross-reactions with other organisms of the nasopharyngeal flora.¹⁷⁵ Because of the lack of sensitivity and specificity, its use is no longer recommended for diagnosis.^{124,552,605}

Since the late 1980s, numerous PCR assays with primers derived from many different chromosomal regions of the organism have been developed for the diagnosis of *B. pertussis*, *B. parapertussis*, *B. holmesii*, and *B. bronchiseptica* infections, and they have been evaluated in multiple studies by comparison with culture and clinically typical pertussis.*

PCR has the advantage of having much higher sensitivity than that of conventional culture. In a prospective study in which swabs for PCR and culture were obtained simultaneously from 555 ill patients with cough, the use of PCR increased the identification of *B. pertussis* infection almost fourfold, from 28 to 111.⁴⁹⁸ Only a few studies have been reported in which the sensitivity and the specificity of PCR for the diagnosis of *B. pertussis* infection were determined by comparison with serologically identified cases.^{252,331,335,469,565} In one study, we compared PCR results with serologic diagnosis and found that PCR had a sensitivity of 61% and a specificity of 88%.¹⁸⁵ Similar findings have been reported from other studies.^{331,335,470,565}

The most commonly used primers for the diagnosis of pertussis include IS 481 and IS 1001.^{123,344,367,546} IS 481 occurs in the genomes of *B. pertussis* (>50 copies) and *B. holmesii* (8–10 copies) but not in *B. parapertussis*. IS 1001 occurs in the genomes of *B. parapertussis* and *B. holmesii* (about 20 copies) but not in *B. pertussis*. The genome of *B. bronchiseptica* usually contains neither IS 481 nor IS 1001. However, in later studies, *B. bronchiseptica* strains were found to contain IS 1001 in their genomes (in the form of an IS 1001–like element called hIS 1001).^{15,192,468,546}

False-positive results are a potential problem with the use of PCR for establishing the diagnosis of pertussis and other respiratory illnesses.^{5,374,410} False-positive results can occur if specimens are opened in the pertussis laboratory before transport to the PCR laboratory.³⁶⁷ False-positive results also can result from contamination of the air in a room in which the previous patient had pertussis and in a room where pertussis vaccine was administered.^{357,545} Moreover, *B. bronchiseptica* can be mistaken for *B. parapertussis* when the IS 1001 primer is used.^{192,468} Rigorous internal and external laboratory controls are necessary, and because insertion sequence elements are somewhat promiscuous, nucleic acid amplification tests should be accompanied with conventional culture.

Obtaining a routine laboratory diagnosis of *B. pertussis* infection for adults or in other atypical cases is hampered by the problem that medical care usually is not sought until the third or fourth week of the illness and antibiotics frequently have been administered before the possibility of pertussis was considered.^{124,393,503} During the past 30 years, the most significant advance in the diagnosis of pertussis has been the development of ELISA.³⁶⁷

Natural infection with *B. pertussis* is followed by a rise in serum concentrations of IgA, IgG, and IgM antibodies to specific

*References 12, 123, 124, 162, 174, 178, 203, 215, 224, 242, 252, 278, 307, 330, 331, 335, 344, 357, 363, 374, 435, 468–470, 484, 498, 499, 545, 546, 552, 565, 564, 567, 605.

antigens of the organism and to preparations of the whole organism.^{134,191,233,356,382,393,441,520,570} In contrast to natural infection, primary immunization of children induces mainly IgM and IgG antibodies and not IgA antibodies.

Serologic testing for *B. pertussis* infection in the clinical setting is not well standardized but is widely available in Europe and North America.¹²⁴ In the research setting, the use of ELISA contributed significantly to establishing the diagnosis of *B. pertussis* infection in many patients with negative cultures.^{156,230,346,347,395,393,503,616} Most useful was the determination of IgG and IgA antibodies to PT and FHA. The most reliable proof of acute infection is the demonstration of a significant increase in antibody values between acute phase and convalescent phase serum specimens. Frequently, because collection of acute phase specimens is delayed and the acute phase values already are elevated, significant increases between first and second serum specimens cannot be demonstrated. However, a diagnosis can usually be established on the basis of a high value or values on a single serum specimen.^{150,393,503,603,616} Because *B. parapertussis* infection induces cross-reacting antibodies to *B. pertussis* FHA, the use of this antigen alone cannot differentiate *B. pertussis* from *B. parapertussis* infection.^{211,520}

Measurement of agglutinating antibodies also is useful for establishing the diagnosis of *B. pertussis* infection, and because the test is simple, inexpensive, and accurate, it can be used in the clinical setting.^{150,257,393,441,503} Unfortunately, its sensitivity is low.

In clinical practice, the laboratory diagnosis of pertussis should be approached as follows. In all cases in which the cough is of less than 2 weeks' duration in adolescents and adults or 3 weeks' duration in children, a nasopharyngeal specimen should be obtained for culture or PCR. For adults who have had cough for more than 2 weeks' duration, single-serum ELISA is the preferred method provided they have not been immunized against pertussis in the previous 12 months.¹²⁴ This method also can be used for children if they have not been immunized within a year.

Many commercial laboratories offer single-serum diagnostic tests for *B. pertussis*, and almost all of the offered tests lack specificity. Any test that employs the whole organism is fraught with false-positive results. Tests that report specific IgM antibodies also are unreliable. The greatest sensitivity and specificity for the serologic diagnosis of *B. pertussis* infection are achieved by ELISA or an ELISA-like test with the measurement of IgG and IgA antibodies to PT. Single high values of IgG or IgA antibodies to PT indicate infection.³⁶⁷ A sensitive and specific test in North America is available from Focus Diagnostics (Cypress, CA).⁴⁶¹ The performances of several European commercial serum ELISA kits for the diagnosis of *B. pertussis* illness have been evaluated by Riffelmann and associates.⁴⁷² They found that three kits that used PT as the antigen had specificities and sensitivities from 80% to 90%.

Not all infected persons develop antibody responses to PT. Approximately 25% of children lack an adequate response, as do approximately 10% of adolescents and adults (J. Cherry, unpublished observation).⁵²⁰

An ELISA has been developed for the detection of IgA antibody to *B. pertussis* in nasopharyngeal secretions as an indicator of recent infection.^{205,210,619} *B. pertussis* IgA appears in nasopharyngeal secretions during the second or third week of illness and persists for at least 3 months.²⁰⁵ However, the appearance of secretory IgA may be delayed in children younger than 1 year of age.⁴¹⁵ This antibody is not induced by primary parenteral *B. pertussis* vaccination. Detection with the use of ELISA of *B. pertussis* IgA in secretions may be a diagnostic aid for culture-negative patients whose symptoms have persisted for longer than 3 weeks. To our knowledge, this test is not clinically available.

TREATMENT

Several antibiotics have in vitro efficacy against *B. pertussis*.^{26,33,32,34,40,80,272,275-277} The first choice for treatment since the 1970s has been oral erythromycin. It ameliorates the symptoms if it is given early during the course of the illness and eliminates viable organisms from the nasopharynx within a few days, thereby shortening the period of contagiousness. Unlike culture, PCR may remain positive for prolonged periods, especially in infants.^{40,44,158,526} The dose for children is 40 to 50 mg/kg per day given every 6 hours for 14 days; the dose for adults

is 2 g/day given every 6 hours for 14 days. A 7-day course of erythromycin estolate was shown in a large Canadian study to be as efficacious as 14 days of treatment.²³²

The newer macrolides also can be expected to be effective.^{9,80} Azithromycin is given as 10 mg/kg on day 1 and 5 mg/kg on days 2 to 5 as a single dose for 5 days for children and 500 mg on day 1 and 250 mg on days 2 to 5 for adults. Clarithromycin is given as 15 to 20 mg/kg per day in two divided doses for 7 days for children and 1 g/day in two doses for 7 days for adults.

Although rare, the use of erythromycin in young infants is associated with hypertrophic pyloric stenosis, and parents need to be educated about the symptoms of this potential risk.^{75,270} Because of the risk, the CDC recommends treating neonates with azithromycin rather than erythromycin.⁸⁰

The CDC's recommended azithromycin dose is 10 mg/kg for 5 days. However, we are not aware of data that support this recommendation rather than what is also suggested for children beyond the neonatal period (10 mg/kg on day 1, followed by 5 mg/kg on days 2 to 5). Pyloric stenosis has been reported in 2 neonates who had received azithromycin (10 mg/kg for 5 days) and we think the reduced dose should be used in neonates on days 2 through 5 of treatment. In a study using the military health system database, erythromycin and azithromycin use within the first 42 days of life had the risk of inducing pyloric stenosis.¹⁶⁴ The erythromycin risk was about 1.5-fold greater than that of azithromycin. Trimethoprim-sulfamethoxazole can be used as an alternative agent in those who cannot tolerate erythromycin or azithromycin.²⁷⁶

The first erythromycin-resistant strain of *B. pertussis* was isolated from a 2-month-old male infant in Yuma County, Arizona, in June 1994.³²⁸ The isolate was highly resistant, with a minimal inhibitory concentration (MIC) greater than 64 µg/mL (the usual MIC of erythromycin is 0.02 to 0.1 µg/mL). Four more resistant *B. pertussis* strains were recovered from cases in California, Utah, and Minnesota.^{220,312,323} In France, macrolide resistance developed during illness in a neonate. In Japan, six *B. pertussis* strains were found to have high-level resistance to nalidixic acid and decreased susceptibilities to fluoroquinolones.⁴³⁴ No evidence of a pattern of emerging macrolide resistance has been seen, but because PCR rather than culture has become the diagnostic method of choice in most laboratories, the chance of missing resistant strains is possible.

Patients infected with *B. parapertussis* and *B. holmesii* should be treated with macrolides, but *B. bronchiseptica* usually is resistant to macrolides, and alternative therapy is necessary.³⁶⁷ *B. bronchiseptica* strains usually are sensitive to aminoglycosides; extended-spectrum, third-generation penicillins; tetracyclines; quinolones; and trimethoprim-sulfamethoxazole.

Historically, no infectious disease has a greater list of remedies lauded as beneficial but without objective evidence of effectiveness than pertussis.^{42,102} Supportive care includes avoidance of factors that provoke attacks of coughing and maintenance of hydration and nutrition. In the hospital, gentle suction to remove secretions and well-humidified oxygen may be required, particularly in infants with pneumonia and significant respiratory distress. For severe infections in neonates and young infants, assisted ventilation is often necessary. However, infants who develop pulmonary hypertension with respiratory and cardiovascular failure respond poorly to aggressive therapy (i.e., pulmonary artery vasodilators and ECMO) and have high mortality rates. Because data suggest that the refractory pulmonary hypertension results from the extreme leukocytosis with lymphocytosis, which is always present in fatal cases, we think that leukocyte-reducing measures such as exchange transfusion should be implemented.^{121,159,218,449,482} Exchange transfusion may be better than leukofiltration because it removes PT and reduces the WBC count.

The use of corticosteroids has received attention in the treatment of pertussis.^{42,625} Cortisone treatment in the murine model of pertussis increased the mortality rate.²⁸³ In a study by Roberts and associates,⁴⁷⁵ dexamethasone treatment did not shorten the course of hospitalization compared with untreated controls.

The use of salbutamol was suggested as having some value, but no benefit was found in three studies reviewed by Bettiol and coworkers.^{42,54} Pillay and Swingle⁴⁵⁰ reviewed the symptomatic treatment of pertussis and found no statistically significant benefit for the use of diphenhydramine, dexamethasone, or salbutamol.

PROGNOSIS

The prognosis for pertussis is related to the patient's age. For older children and adults, the prognosis is good, but infants have a significant risk of death and development of encephalopathy.* Long-term follow-up suggests that apnea or seizures at the time of disease in children may be associated with subsequent intellectual impairment.⁵³⁵ A Danish study found that the risk of epilepsy was increased among children with hospital-diagnosed pertussis infection compared with the general population.⁴⁴⁰ The current availability of pediatric intensive care units and assisted ventilation has reduced the rate of mortality among infants who receive medical care.²⁵³ Unfortunately, many deaths occur outside the hospital. No evidence has shown that pertussis impairs ventilatory function later in life.²⁵³

PREVENTION

Vaccine Efficacy

Whole-Cell Vaccines

The first pertussis vaccines were developed in the 1920s, and effective vaccines have enjoyed worldwide use since the 1940s.^{89,88,113,367} After World War II, extensive vaccine trials were organized by the British Medical Research Council.^{375–377} Based on these studies and smaller studies in England, the United States, and other countries, DTP vaccine use became routine in many countries.¹⁸⁶ The pertussis attack rate was relatively constant in the United States in the prevaccine era between 1922 and 1942. From 1943 to 1976, a 150-fold reduction in the attack rate was associated with widespread childhood pertussis immunization.

The relationship between vaccine use and disease control also was supported by data from England and Wales. The pertussis attack rate declined between 1958 and 1973 and increased dramatically between 1977 and 1983 after a marked decrease occurred in the number of vaccinations administered beginning in 1974.⁸⁹ The attack rate decreased with the widespread use of vaccine and increased when vaccine use decreased. Moreover, the attack rate after the decrease in vaccine use was increased most markedly in the newly susceptible cohort of children younger than 4 years of age.

In the 1980s, numerous household contact studies were performed.^{67–69,150,442} In a study from 1982 to 1983 involving 440 household contacts between the ages of 6 months and 9 years, the secondary attack rate among unvaccinated contacts was compared with the rate for children who had received three or more DTP doses. Vaccine efficacy was 91.4%. A similar study conducted during the period of 1979 to 1981 revealed an efficacy of 82.4%.

In another study, Onorato and associates⁴⁴² found that the calculated efficacy varied markedly according to the clinical case definition. Efficacy against any cough was 63%, whereas it was 83% if a cough duration of 21 or more days was required.

In the 1990s, the most definitive studies of vaccine efficacy of DTP and DTaP were performed in four countries.^{212,222,249,335,502,509,520} In these trials, the efficacy of the candidate DTaP vaccines was compared with the efficacy of DTP vaccines; the controls were subjects who received DT. With the exception of one lot of one DTP vaccine (Connaught, USA) that had poor immunogenicity, the DTP vaccines were more efficacious than the DTaP vaccines. The poor efficacy of the Connaught DTP vaccine probably was the result of an unusual low-potency lot of this vaccine rather than a generic problem with the vaccine.³⁶⁷ In a case-control study in the United States, the efficacy of the Connaught vaccine was similar to that of the Wyeth-Lederle DTP vaccine, which in the controlled trial in Germany had a high level of efficacy.⁴⁷ In a large comparative trial, the DTP vaccine from England (Evans vaccine) had long-term efficacy greater than those of the three DTaP vaccines with which it was compared.⁴³⁷

Acellular Vaccines

Research in the 1970s showed that three *B. pertussis* antigens (i.e., PT, FHA, and LPS) were liberated into the medium during culture and that

the antigens could be concentrated and separated by density-gradient centrifugation.^{113,264} This finding enabled development and production of vaccines by six manufacturers in Japan.^{119,303,429,494} All six vaccines had minimal or no endotoxin but different amounts of PT and FHA. Some of the vaccines were found to contain FIM 2 and PRN.

Despite limited proof of efficacy, the six vaccines were put into routine use in Japan in 1981, and they have controlled to some degree reported epidemic pertussis during the ensuing decades. However, because adequate data were not available on any single vaccine or on vaccine use in young infants, many extensive trials were performed subsequently in Europe, Africa, and Japan.^{3,212,222,249,332,408,509,520}

After extensive analysis of the data from the original efficacy trial in Sweden in the mid-1980s, it was found that calculated efficacy varied significantly, depending on the clinical case definition and the laboratory methods.^{3,48,230,527,528,530} Researchers decided that a universal primary case definition should be developed for use in all subsequent efficacy trials so that different vaccines in different trials could be compared.

A World Health Organization (WHO) committee met in Geneva in January 1991, and a primary case definition was developed.⁶¹³ This definition and minor variations of it were used in the efficacy trials in the 1990s. The WHO case definition was as follows:

1. An illness with 21 days or more of spasmodic cough and either culture-confirmed infection with *B. pertussis* or serologic evidence of infection with *B. pertussis* as indicated by a significant rise in IgA or IgG antibody by ELISA against PT or FHA in paired sera or
2. Contact with a case of culture-confirmed pertussis in the household with onset within 28 days before or after the onset of cough in the study vaccinee.

Not all members of the WHO committee, including Cherry, agreed with this primary case definition because its use results in the elimination of many laboratory-confirmed cases from efficacy calculations.^{96,247,251,527,528,530} With this definition, vaccines that lessen the severity of disease but are poor at preventing mild disease were overrated.

In 1994 and 1995, seven efficacy trials with candidate DTaP vaccines in four countries were completed.^{212,222,332,502,509,520,553} and an additional trial in Sweden was completed in 1997.⁴³⁷ As shown in Table 129.3, the nine vaccines are different in the number of antigens that they contain and in the concentrations of the specific antigens. In all efficacy studies, confounding factors may affect the results. Double-blind studies with placebo and whole-cell vaccine controls are ideal. However, placebo control was not ethical in countries in which DTP vaccine was recommended. Studies in Germany and Senegal therefore used various methods to obtain efficacy data despite the lack of a blinded diphtheria-tetanus (DT) toxoid group. Observer bias can affect the results of all studies, including those with a double-blind control. For example, a less efficacious vaccine that prevents typical disease but not mild disease can be determined to be more efficacious than it actually is if the study observers believe they “know pertussis” and dismiss atypical cases as being other respiratory tract illnesses and do not obtain cultures or conduct proper follow-up.¹¹⁸

Household contact studies, unless they are nested analyses in prospective cohort studies, also are subject to observer bias, and case-control studies result in significantly inflated efficacy percentages.^{96,118,120,183,186,408} In cohort studies, observer bias by parents can be reduced by frequent prospective telephone contact with study families. A serologic diagnosis and a diagnosis by culture increased the identification of mild cases, which are more likely to occur in vaccinees than in control subjects.

A summary of the efficacy data for 10 acellular pertussis vaccines evaluated in the eight trials performed in the 1990s and the earlier 1980s' Swedish trial is presented in Table 129.4. The data in this table indicate that three- and four-component vaccines (i.e., vaccines containing PRN, FIM, PT, and FHA) have greater efficacy against *B. pertussis* illness (i.e., mild and typical) than do the PT or PT/FHA vaccines. The apparent high efficacy of the two-component vaccine (Tripedia) in the Munich study³³² can be explained by the type of study (i.e., case-control study), significant observer bias, the vaccine contents (i.e., PRN, FIM, PT, and FHA), and the lack of serologic diagnosis.

The study done in Stockholm was a comparative study without a DT control group.⁴³⁶ In this trial, in which vaccines were administered to children at 3, 5, and 12 months of age, the efficacy of CCL DTaP5

^aEfficacy against typical pertussis based on positive culture without serologic analysis.^bSignificant observer bias occurred in this trial.⁵⁶^cLaboratory diagnosis based on culture only; 80% efficacy was against illness with cough of 21 or more days, and 93% efficacy was against the World Health Organization (WHO) case definition.^dThirty-one percent efficacy based on 21 days or more of illness with cough; 74% efficacy was against the WHO case definition.

(i.e., five-component vaccine) was significantly better than that of Acelluvax (i.e., three-component vaccine) and was not significantly different from that of the comparative DTP vaccine (i.e., Evans vaccine) for the initial 3 years of follow-up. Acelluvax had greater efficacy than did the two-component vaccine SKB-2.

Follow-up studies of the various efficacy trials have been done in Sweden, Italy, and Germany, and all suggest sustained protection.^{223,348,436,492,493} In a study by Gustafsson and associates,²²² members of a large cohort vaccinated at 3, 5, and 12 months in the 1993 to 1996 trial were observed from October 1997 to September 2004. Overall, good protection lasted for approximately 5 years. The tabular data in this report suggest that Acelluvax had efficacy similar to that of CCL DTaP5. However, when all the data from the original trial and the follow-up data were combined, the overall attack rate for children who had received CCL DTaP5 was lower (47.5 cases/100,000 people) than that for children who had received Acelluvax (59.7 cases/100,000 people). This difference was not significantly different, however. The Evans DTP vaccine had greater sustained efficacy than Acelluvax or CCL DTaP5.

It appeared that DTaP vaccines that contained PRN had relatively good efficacy for approximately 5 years but that (with the exception of one lot of one DTP vaccine) DTP vaccines usually were more efficacious.^{212,222,332,437,492,502,509,520}

In 2005, two acellular pertussis component, diphtheria, and tetanus toxoid vaccines (i.e., Tdap vaccines) became available for use in adolescents and adults.^{81,82,100,189,190,246} The components of the Adacel and Boostrix vaccines are given in Table 129.5. After a single dose, both vaccines elicit vigorous antibody responses to the antigens that they contain. These responses are significantly greater than those observed in infants at 7 months of age after they have received three doses of the DTaP vaccines (i.e., Daptacel and Infanrix) of the two manufacturers.

In a double-blind efficacy trial enrolling adolescents and adults, an acellular pertussis vaccine (without diphtheria and tetanus toxoids) with the same concentrations of PT, FHA, and PRN as Boostrix had an efficacy of 92%.⁵⁷⁸ However, the data safety monitoring board allowed the removal of one case that occurred in a vaccinee. If this case is included, the efficacy is approximately 78%. No similar efficacy trial

TABLE 129.5 Antigenic Composition of Adacel and Boostrix per 0.5 mL of Vaccine

Antigen	Adacel	Boostrix
Diphtheria toxoid	2 Lf	2.5 Lf

was done with Adacel or its acellular pertussis components. However, extensive epidemiologic data from Canada, where Adacel has been used since 2003, show a marked reduction of pertussis among adolescents.²⁹⁵

The 2010 epidemic of pertussis in California and more recent outbreaks in other states and Australia led to several studies of DTaP and Tdap vaccine failure and vaccine effectiveness.^{73,464,587,608} In a study by Wei and associates, Tdap vaccine effectiveness in school children 11 years of age and older was 66%.⁵⁸⁷ However, because the sample in this study was small, the result was not statistically significant. In a study of adolescents, Tdap effectiveness was found to be 78%.⁴⁶⁵

Reported cases of pertussis started to increase around 1982 to 1984. This was about 14 years before the universal use of DTaP vaccines. However in the DTaP and Tdap vaccine era, there have been marked peaks in reported pertussis incidence in 2005, 2010, 2012, and 2014. Numerous publications indicated that DTaP vaccines were inferior to DTP vaccines in regard to sustained efficacy.^{105,109,305,306,334,397,544,600,601,607} Although a major part of the increase in reported pertussis resulted from greater awareness and the use of PCR and single-serum serologic diagnoses, there are several deficiencies in DTaP vaccines compared with DTP vaccines. Tdap vaccines have efficacy that wanes rapidly during a 3-year period.^{35,311}

Box 129.2 shows five factors that contribute to the diminished efficacy of DTaP vaccines compared with DTP vaccines. The first is the type of T-cell response. The difference in T-cell response after infection, DTaP vaccination, and DTP vaccination was described more than 25 years ago by Kingston Mills and associates^{486,490} in studies using a mouse model. These findings were largely ignored, but later studies using baboons confirmed and expanded what was previous demonstrated.^{580–582} Previously infected baboons and DTP-vaccinated baboons possess strong *B. pertussis*-specific helper T-cell type 17 (Th17) memory and Th1 memory (i.e., Th17/Th1 response), whereas DTaP vaccinees had a Th1/Th2 response. The Th17/Th1 response prevents infection and disease, whereas the Th1/Th2 response prevents only disease. The Th17/Th1 response also gives longer protection than a Th1/Th2 response.

The next factor is an incomplete antigen package. From the vaccine efficacy trials in the 1980s and 1990s, it was clear that increasing the number of proteins in a DTaP vaccine increased its initial efficacy.⁹⁶ The two DTaP vaccines currently used in most of the world contain three and five proteins. In contrast, DTP vaccines contain more than 3000 proteins, and it is likely that antibodies to many of them contribute to protection.

Another important factor is the incorrect balance of antigens in the vaccines. Of the eight vaccine efficacy trials of the 1990s, only two were done in such a way that serologic correlates of immunity could be determined.^{96,529} The two studies were done independently, but they yielded similar findings. Both found that antibody to PRN and FIM induced protection in about 70% of vaccinees. Both also found that antibody to FHA did not contribute to protection. Both studies confirmed that high levels of antibody to PT blocked the effectiveness of antibody to FIM. This blocking effect was also observed for PT and PRN in the Swedish study (J. Cherry, unpublished data, 2005). Studies by Weiss and colleagues⁵⁹¹ using serum from the adult aP vaccine trial supported the idea that antibody to PT had a blocking effect on antibody to PRN. We suspect the same blocking effect relates to PT and FIM. Two highly effective DTP vaccines produce only low levels of antibody to PT and

BOX 129.2 Factors That Lessen Efficacy of DTaP Vaccines Compared With DTP Vaccines

- A Th1/Th2 response in DTaP vaccinees versus a Th17/Th1 response in DTP vaccinees
- Incomplete antigen package
- Incorrect balance of antigens in the vaccine
- Linked-epitope suppression
- Genetic changes in *B. pertussis*

Th1, Helper T cell type 1; Th2, helper T cell type 2; Th17, helper T cell type 17.

FHA, whereas the currently used DTaP vaccines produce high levels of antibody to PT and FHA, which may suppress efficacy.

The fourth factor reducing vaccine efficacy is linked-epitope suppression. In conjunction with colleagues in Sweden, we described this in 2010.^{117,125} We found that people who received a PT toxoid vaccine but were vaccine failures developed antibody to PT but not to FHA, a nonvaccine antigen. Similarly, when people received a PT/FHA-containing vaccine and were vaccine failures, they developed antibody to PT and FHA but not to PRN and FIM 2/3.

With linked-epitope suppression, memory B cells outcompete naive B cells for access to the *Bordetella* epitopes because they are more numerous and their receptors exhibit a higher antigen affinity. Linked-epitope suppression applies as the immune response to novel epitopes is suppressed by the strong response to initial components if they are introduced together.

Findings by Sheridan and associates⁵⁰⁷ in Australia support the linked-epitope suppression hypothesis. They found over a 12-year period that the pertussis attack rate among DTP-primed children was significantly less than it was among DTaP-primed children.

The fifth factor is genetic changes in *B. pertussis* proteins. In the whole-cell vaccine era, this was never a problem because immunizations resulted in an antibody response to multiple antigens. However, it is a potential problem for DTaP vaccines. Three genetic changes have occurred in the era of acellular vaccines: shift in the *ptx* P1 allele to the *ptx* P3 allele, increase in *fim* 3B strains in the United States, and the occurrence of PRN-deficient mutants. Of these, only the circulation of PRN-deficient mutants is important. In the United States, almost all circulating strains are PRN deficient. Because the main protective antigen in three-component vaccines is PRN, more vaccine failure with three-component vaccines might be expected, but that has not been demonstrated because antibody to the B subunit of PT provides considerable efficacy against typical pertussis.

A Wisconsin study showed that efficacy of Tdap vaccines waned over a 3-year period.³¹¹ This was a surprise to many people because in the adolescent and adult efficacy trial (APERT), antibody to PRN persisted for about 9 years. This led to the suggestion that administering Tdap about every 10 years would decrease circulation of *B. pertussis*.^{321,578} This prediction was wrong. The antibody to PRN determined by ELISA is probably cross-reacting antibody to *Bordetella* sp. and other organisms, and the cross-reacting antibody that was measured did not protect against *B. pertussis* infection.

Adverse Events

Whole-Cell Vaccines

Local reactions and relatively mild systemic complaints are frequent occurrences after pertussis immunization. Less commonly, severe neurologic illness and death have been temporally associated with DTP immunization.

The largest study in the United States, which was designed to assess the risk for relatively common and uncommon reactions to pertussis vaccine, was performed by Baraff and associates.^{22–25,129} It was conducted between January 1978 and December 1979. Reactions in children who received DTP or DT immunization were compared. A total of 15,752 DTP immunizations and 784 DT immunizations were given to children 2 months to 6 years of age. They were evaluated for reactions that occurred within 48 hours of vaccine administration. All common local

and systemic reactions occurred more frequently in the DTP recipients than in the DT group. Differences between the common reactions in the two groups were all highly significant ($P < .005$).

Redness at the injection site occurred in 37.4% of DTP recipients and in 7.6% of DT vaccinees. Fever ($\geq 38^\circ\text{C}$ [100.4°F]) occurred in 46.5% of DTP recipients. A temperature of 39°C (102.2°F) or higher occurred in 6.1% of DTP recipients but in only 0.7% of DT recipients. Drowsiness, fretfulness, vomiting, anorexia, and persistent crying were other reactions recorded for 3.1% (i.e., persistent crying) to 53.4% (i.e., fretfulness) of DTP recipients versus 0.7% (i.e., persistent crying) to 22.6% (i.e., fretfulness) of DT vaccinees. Rates of local reactions, but not those of systemic reactions (except fever), increased from dose to dose in an immunization series.

Another 0.1% of DTP recipients in this study were reported by the parents to have a high-pitched, unusual cry; 0.06% had convulsions, and 0.06% had hypotonic-hyporesponsive episodes (e.g., shock, collapse). No children in the control group (i.e., DT recipients) had similar reactions; however, the control group was of modest size (784 DT recipients), and statistical significance could not be assigned to any of these relatively uncommon events.

Because convulsions in young children are the result of many different etiologic factors, the cause-and-effect relationship with pertussis vaccine is less clear. However, inasmuch as fever develops in almost one half of all DTP vaccinees and febrile convulsions are not uncommon events, a reasonable assumption is that many convulsions that are temporally associated with DTP vaccination are induced by the immunization. Three studies found a significant association between pertussis immunization and febrile convulsions.^{27,508,574} Approximately 1 of 1000 vaccinees older than 6 months of age has a first febrile seizure after receiving pertussis immunization. The concomitant use of acetaminophen (15 mg/kg per dose at the time of immunization and every 4 hours for 24 hours) with DTP vaccination has been suggested as a means of reducing the incidence of febrile convulsions in vaccinees.³²⁷

Neurologic disease and death temporally associated with pertussis immunization have been major concerns throughout the vaccine era. During last 60 years of the 20th century, several case series and individual cases of neurologic illness occurring after receipt of pertussis immunization were reported, and by 1979, more than 1000 cases of alleged neurologic damage induced by pertussis vaccine were reported.^{39,60,86,89,315,362,599} Few of these reports had evidence of an adequate search for other possible causes of the neurologic disease, and in none were data available for rate calculations.

From 1967 to 1980, several attempts were made to determine the frequency of neurologic disease after receipt of pertussis immunization.^{4,89,165,166,188,238,524,533} However, because controls were not included in any of the population evaluations, all rate estimates included children with temporally related events that had other causes.

A carefully designed, prospective, case-control study (i.e., National Childhood Encephalopathy Study [NCES]) of all hospital admissions of children 2 to 35 months of age with acute, serious neurologic disorders in England, Wales, and Scotland was undertaken between 1976 and 1979.^{6,37,351,384,385,388,389} The results of this study for the first time revealed an apparent statistical association between pertussis immunization and neurologic illness. Researchers found that a child who had received DTP vaccine within the previous 3 to 7 days was two to five times more likely to have neurologic disease than was a child who was not immunized during the same interval. However, the causal relationship between DTP immunization and neurologic illness found in this study must be questioned because cases and controls had an equal frequency of immunization during the month preceding the index date. A more appropriate interpretation of the results is that they do not indicate cause and effect; rather, the DTP immunization highlights something that will occur anyway but moves it forward in time (i.e., trigger effect).^{90,91}

Cases of infantile spasms, an identifiable seizure disorder of infancy, usually occur in the 6-month period from 2 to 7 months of age; it is therefore not surprising that some cases occur after DTP immunization. Simple calculations indicate that approximately 12% of all patients destined to have infantile spasms between 2 and 7 months of age will have an onset of illness within 7 days after receiving DTP immunization. The temporal association between DTP immunization and infantile

spasms has led many people to assume a cause-and-effect relationship. However, controlled data from the NCES in Great Britain provide strong evidence against a causative role for pertussis vaccine in infantile spasms.³⁷ In a Danish study, Melchior³⁷⁸ found that the time of onset of infantile spasms was not altered when the time of pertussis immunization was changed from 5, 6, 7, and 15 months of age to 5 weeks, 9 weeks, and 10 months of age. In both periods, 42% of patients had the onset during the first 4 months of life.

Data from the NCES were reanalyzed with the exclusion of cases of infantile spasm.^{385,389} From these analyses, the risk of permanent brain damage occurring from pertussis immunization was suggested to be 1 case per 330,000 vaccine doses, and the risk of encephalopathy has been estimated to be 1 case per 140,000 vaccinations. However, a review of the NCES data by other investigators indicates that both rate estimates are incorrect. Stephenson⁵²³ showed that the 1 case per 140,000 vaccine doses rate for all encephalopathy is an artifact resulting from the inclusion of nine children with febrile convulsions. Similarly, MacRae³⁵⁰ found that the increased relative risk that was observed within 7 days of receiving immunization (which was used to calculate the risk for brain damage of 1 case per 330,000 immunizations) was offset by a decreased relative risk over the subsequent 3-week period. This finding, similar to the original study data and the infantile spasm data, indicates a redistribution of events over time rather than a cause-and-effect relationship.

In the United States, the major neurologic illness that was temporally associated with DTP immunization was the first seizure of what turned out to be severe epilepsy. By chance, this association may occur 400 times per year in the United States. Four carefully performed studies that included approximately 330,000 children and 1 million immunizations have examined the possibility that pertussis immunization is a causative factor in epilepsy; no evidence of a causative role has been found.^{91,198,214,508,574} Two large studies in the United States and Canada found no evidence of a causal association with DTP immunization and encephalopathy.^{402,466}

Similar to infantile spasms, SIDS occurs in early life, and cases that occur after administration of DTP immunization are not surprising. Hoffman and associates²⁶⁸ performed an extensive, prospective, case-control study of risk factors in SIDS from October 1978 through December 1979. In this study of 800 cases, investigators found that DTP immunization was not a risk factor for development of the syndrome. Other good, controlled studies have yielded similar results.^{113,213} No evidence has demonstrated that DTP vaccinees have an increased risk of developing asthma later in life.²⁶¹

Acellular Vaccines

An extensive amount of reactogenicity information was generated in phase II and phase III studies with all licensed DTaP vaccines.^{148,212,222,332,471,501,556} Because endotoxin has been removed from all DTaP vaccines, it is not surprising that all are less reactogenic than DTP vaccines. In a double-blind study, the reactogenicity of 13 DTaP vaccines was compared with the reactogenicity of a DTP vaccine.¹⁴⁸ This study involved 2200 infants; 113 to 217 received an acellular product, and 370 received the whole-cell vaccine. Study participants received three doses of vaccine at 2, 4, and 6 months of age. Overall, all monitored reactions except vomiting occurred less frequently and were less severe in DTaP recipients than in DTP recipients. Results from this study are presented in Table 129.6. Local redness and swelling and fever increased in frequency from the first to the third dose, whereas the complaint of drowsiness decreased.

In our efficacy trial in Germany with Accl-Immune, we monitored reactions in more than 8000 children after receipt of four doses of vaccine at 3, 4.5, 6, and 15 to 18 months.^{504,556} For the first three vaccine doses, the findings were similar to those shown in Table 129.6. After the fourth dose, the frequency of occurrence of local erythema and induration and fever increased considerably compared with their frequencies after the third dose. Ten percent of DTaP recipients had local erythema of 2.4 cm or greater, and 28% had temperatures of 38°C or higher. Other investigators also found an increased frequency and severity of local reactions occurring after administration of the fourth and fifth doses of DTaP vaccines.^{248,288,448,471,501} Of particular concern is the observation of extensive swelling of the thigh with booster doses of

some DTaP vaccines.^{471,501} Rennels and associates⁴⁷¹ found that swelling occurred more commonly after immunization with DTaP vaccines containing high amounts of diphtheria toxoid. With Acel-Immune, a vaccine with a low diphtheria toxoid content, 15.4% of subjects had induration of more than 5 cm but less than 10 cm after receiving a fifth dose; swelling of the entire limb did not occur.²⁴⁸

In five of the efficacy trials in the 1990s, the occurrence of less common, more severe events (i.e., persistent crying, seizures, and hypotonic-hyporesponsive episodes) was monitored. These data are summarized in Table 129.7. Temporally related persistent crying, hypotonic-hyporesponsive episodes, and seizures were rare events after receipt of immunization with DTaP vaccines. In a large active surveillance program (IMPACT), researchers found that risks of having febrile seizures and hypotonic-hyporesponsive episodes after receiving pertussis-containing vaccines decreased significantly after the introduction of DTaP vaccines in Canada.³²⁶ In a Vaccine Safety Datalink study, Huang and coworkers²⁸⁰ did not observe an increased risk of seizures in children 6 weeks to 23 months of age after DTaP vaccination.

Schedules and Contraindications

Immunizing schedules for whole-cell and acellular pertussis vaccines vary throughout the world.³⁸⁶ Before the acellular vaccine era, schedules related to DTP vaccines were determined to some measure by concern relating to true and perceived reactions.^{94,127,180,386} An immunization schedule involving only three doses given to infants at 2, 3, and 4 months of age was quite effective in controlling pertussis-related morbidity and mortality in the United Kingdom.^{61,562} However, the five-dose schedule used in the United States resulted in lower attack rates in preschool- and school-aged children.^{89,113}

A World Health Organization position paper⁶¹⁴ suggests that countries that have been using DTP vaccines continue to do so. They recommend a three-dose primary series with the first dose administered as early as 6 weeks of age. Subsequent doses are recommended to be given 4 to 8 weeks apart at age 10 to 14 weeks and 14 to 18 weeks.

The recommendation for the DTaP vaccine in the United States is that it be given in the same five-dose schedule as previously recommended for DTP vaccines.^{9,70} However, follow-up data from the 1990s efficacy trials and reactogenicity data suggested that this approach could be modified.^{212,222,436,492,493,501,543,553} Our findings for Acel-Immune suggested that the current five-dose schedule was appropriate.^{348,520} Conversely, data from other trials suggested that administration of the fourth dose of some vaccines could be postponed until the child was 4 to 6 years of age or that the third dose could be moved back to the child's second year of life.^{223,436,437,492,493,543,553} These changes would not be expected to decrease efficacy but would decrease troubling local reactions with booster doses. However, the follow-up data for the previously described studies employed passive surveillance techniques, and pertussis attack rates in DTaP recipients were likely underestimated. Data from the 2010 California epidemic show a yearly increase in vaccine failures after the fifth dose of DTaP.^{104,601} A DTaP vaccination schedule used in several countries is to administer the vaccine at 3, 5, and 12 months of age.

Acellular pertussis-component quadrivalent (DTaP, IPV), pentavalent (DTaP, IPV, HBV; DTaP, IPV, Hib), and hexavalent (DTaP, IPV, HBV, Hib) vaccines are available in many countries.¹⁶⁸ In the United States, the following multicomponent vaccines are used: DTaP/IPV/HBV (Pediarix) and DTaP/IPV/Hib (Pentacel). Multicomponent vaccine use should be encouraged to reduce the number of injections that a child receives.⁹

In addition to providing childhood immunization, the availability of adolescent and adult Tdap vaccines allows the vaccination of adolescents and adults to be conducted.* The schedule for the use of Tdap vaccines varies in different countries.^{189,190,246} The most common recommendation is for universal immunization of preadolescents and adolescents and the selective immunization of adults. We previously thought that a universal program involving all preadolescents or adolescents and adults every 10 years would be necessary to prevent the transmission of *B. pertussis* effectively to unimmunized infants and to prevent the continued circulation of *B. pertussis* in a population. However, the recent findings that Tdap vaccine effectiveness lasted only 3 years indicates our previous opinion was wrong. No country has an effective program for universal immunization of adults, and no country is likely to achieve a universal Tdap booster program with even modest compliance. Because adults are the main source of pertussis for young infants, various cocooning programs have been suggested.^{9,72,216,559} They include postpartum immunization of the mother and, if possible, the father; attempts to vaccinate grandparents; and immunization of mothers-to-be during the second or third trimesters of pregnancy. Also considered is lowering the age of infant immunization, including a dose shortly after birth.^{24,31,38,58,59,236,308,609,610} All of these cocooning programs have numerous logistical difficulties.^{463,559}

We think the most promising approach is immunization of the mother during the second and third trimesters of pregnancy. In 2011, the Advisory Committee on Immunization Practices (ACIP) updated its Tdap recommendations to include pregnant women. They suggested giving the vaccine during the third trimester or late second trimester.⁷² In 2013, the ACIP made an additional recommendation: Providers of prenatal care should implement a Tdap immunization program for all pregnant women. Tdap should be administered during each pregnancy. Vaccine should be administered between 27 and 36 weeks' gestation.⁷¹ Two studies in England found that Tdap in pregnancy had an effectiveness of more than 90% in preventing pertussis in infants during the first 2 months of life.^{10,143}

Tdap immunization in all pregnancies can be expected to prevent virtually all pertussis deaths of infants during the first 2 months of life. Unfortunately, the use of Tdap vaccines in pregnant women in the United States is far from optimal.¹¹⁰

Tdap immunization of pregnant women is safe and elicits excellent antibody response to PT and other vaccine antigens.^{301,412,534} Tdap immunization during pregnancy blunts the infant's response to DTaP antigens and some conjugate vaccines.³¹⁸ However, if booster doses are given early in the second year of the life, this is not a problem.^{24,58,107}

Over the years, pertussis vaccine recommendations have undergone many changes. Contraindications to pertussis immunization continue to evolve, but few scientific data support any of the current contraindications. The primary goal of national immunization program in the United States is to vaccinate all infants, children, adolescents, and pregnant women and selected adults. If excessive contraindications and their overinterpretation lead to a large number of unimmunized persons, the programs will fail, and the children in greatest need of protection will contract pertussis. In the United States, the most recent recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics should be followed.

There is considerable pessimism about DTaP vaccines because of their deficiencies. However, this should be put into perspective. There are about 20-fold fewer cases of pertussis today than in the prevaccine era, and illness in cases of DTaP vaccine failure is less severe than illness in unvaccinated children.^{28,105,381,549} We should continue to use DTaP and Tdap vaccines as currently recommended. The DTaP schedule in the United States is 2, 4, 6, and 15 months and at 4 to 6 years of age. However, the first dose can be given at 6 weeks of age, and vaccinating at 6 weeks of age rather than 2 months of age can decrease death, hospitalization, and severe illness. We therefore suggest using this acceleration of the schedule.

Preventing deaths and severe disease in infants too young to be vaccinated is our highest priority. In the past, protecting young infants

by maternal postpartum Tdap immunization and immunizing persons who had contact with young infants (i.e., cocooning) was pushed. However, immunizing pregnant women with Tdap between 27 and 36 weeks' gestation at each pregnancy, if universally applied, would prevent virtually all young infant pertussis deaths.

We also recommend giving Tdap every 10 years rather than using Td. It also seems reasonable to immunize some adults with Tdap every 3 years. They include health care workers and others who have contact with young infants.

Isolation and Prophylactic Measures

Erythromycin, azithromycin, or clarithromycin treatment in the index case shortens the duration of communicability of the organisms and limits spread of the disease. During the first few days of treatment, contact with susceptible persons should be avoided. Close contacts (e.g., household members, those in childcare centers, playmates) of the index case should be protected from infection. Protection can be implemented by the prophylactic use of erythromycin for 14 days, azithromycin for 5 days, or clarithromycin for 7 days.^{9,80,367,522} Active immunization of all exposed persons (i.e., children, adolescents, and adults) who are not adequately vaccinated should be conducted.

The use of prophylactic antibiotics in adolescents and adults in exposure situations such as classrooms and hospital settings frequently is recommended. This approach often involves many people and considerable expense.

Because of the side effects of erythromycin and other macrolides, adult compliance is poor. These antibiotics should not be used prophylactically in large group settings but should be used for treatment only at the first sign of respiratory illness in those exposed.

OTHER *BORDETELLA* INFECTIONS

Bordetella parapertussis Infection

B. parapertussis infection in children can cause unrecognized infection, mild pertussis, or typical pertussis.³⁶⁷ We studied 38 children with *B. parapertussis* illnesses and compared their illnesses with those occurring in 76 children with *B. pertussis* illnesses.²⁵⁶ The results (*B. pertussis*/*B. parapertussis*) were as follows: cough for longer than 4 weeks, 57%/37% ($P = .06$); whooping, 80%/59% ($P = .07$); whooping for longer than 2 weeks, 26%/18% ($P = .05$); paroxysms, 90%/83%; and posttussive vomiting, 47%/42%. Mean leukocyte and lymphocyte counts were 12,500/mm³ and 7600/mm³ and 7800/mm³ and 3500/mm³ ($P < .0001$), respectively.

In an Italian study, children with *B. parapertussis* infection had the following findings: cough (100%), paroxysms (76%), whooping (33%), posttussive vomiting (42%), apnea (29%), and cyanosis (12%).³⁶⁴ All of these rates except cough and paroxysms were lower in children with *B. parapertussis* infections than in children with *B. pertussis* infections. Concomitant infections with *B. pertussis* and *B. parapertussis* can occur.^{273,286,380,623}

Before and during the early pertussis vaccine era, pertussis caused by *B. parapertussis* was considerably less common than that caused by *B. pertussis*.³⁶⁷ For example, during a 16-year period in the Grand Rapids area of Michigan, 4483 cases of pertussis were caused by *B. pertussis*, and 106 cases were caused by *B. parapertussis*.¹⁷² During the DTaP vaccine efficacy trials in Europe, the comparative rates of illness caused by *B. pertussis* or *B. parapertussis* were examined. In a German trial, the rate of pertussis caused by *B. parapertussis* infection in control children was 0.9 cases per 100 person-years.⁵²⁰ Of 130 culture-confirmed cases, 21% were caused by *B. parapertussis*. The percentage of cases caused by *B. parapertussis* in five other trials varied from 2.1% to 20%.³⁶⁴

Until recently, reported pertussis caused by *B. parapertussis* has been an uncommon finding in the United States. During the period of 2008 to 2010, clinical specimens from nine states were tested by PCR for *B. pertussis* and *B. parapertussis* in a commercial laboratory.¹²³ Of the positive samples, 13.9% were identified as *B. parapertussis*. The *B. parapertussis*-positive samples had no seasonal periodicity, whereas the *B. pertussis*-positive samples occurred between weeks 22 and 38 each year. In this study, the ages of the *B. parapertussis* patients were younger

*References 81, 82, 93, 94, 97, 99, 100, 101, 189, 190, 234, 246, 297, 367, 487.

than 5 years (66%), 5 to 10 years (28.7%), 11 to 20 years (3.8%), and 21 years or older (0.4%). In contrast, the *B. pertussis* positivity rates by age were younger than 5 years (38.5%), 5 to 10 years (28.3%), 11 to 20 years (22.2%), and 21 years or older (10.9%). In contrast to the lack of the demonstration of cyclic peaks in this United States study, Kurova and associates³¹⁶ identified *B. parapertussis* cyclic peaks in 1995, 2000, 2003, and 2007 in Saint Petersburg, Russia.

In Wisconsin from 2011 through 2012, 443 *B. parapertussis* infections were reported.³¹⁰ For the 218 patients investigated, it was found that macrolide antibiotic treatment within 0 to 6 days after cough onset significantly shortened the duration of illness. The median duration of the illness in these patients was 10 days, whereas the median duration was 19 days in untreated patients.

In a study in central Ohio carried out in 2010 and 2011, it was found that the *B. parapertussis* cases were significantly younger (mean, 3.5 years of age) than the *B. pertussis* cases (mean, 7 years of age).⁵¹⁵ In a 2009 through 2011 study in Poland, the highest rate of *B. parapertussis* infection was in children 3 to 5 years of age.⁵⁵⁰

B. parapertussis bacteremia has been reported in two 6-year-old boys.⁵⁷⁶ One patient had rhinovirus coinfection and had been receiving steroids for asthma, and the other patient had acute lymphoblastic leukemia.

Bordetella bronchiseptica Infection

B. bronchiseptica causes respiratory tract infections in at least 18 mammalian species.¹³⁷ Most notable are atrophic rhinitis in pigs, kennel cough (i.e., rhinotracheitis) in dogs, and bronchopneumonia in rabbits and other laboratory animals.

In 1911, McGowan³⁷² observed that laboratory workers exposed to various animals with *B. bronchiseptica* infections occasionally had respiratory tract illness. In 1926, a 5-year-old girl with a pertussis-like illness was found to be infected with *B. bronchiseptica*.⁵⁷ Her illness began 10 to 12 days after she had been given a rabbit with mild “snuffles.” Otherwise healthy children who became infected with *B. bronchiseptica* after being exposed to farm animals or pets usually have pertussis-like illnesses.³⁶⁷

In 2008, Rath and coworkers⁴⁶⁵ described an infant who had recurrent episodes of pertussis-like illness due to *B. bronchiseptica* that cleared after imipenem therapy. In a separate study, another immunocompetent infant with recurrent pertussis-like illness was described.¹⁵²

Occasional infections with *B. bronchiseptica* in humans have been reported during the past 40 years, with most occurring in immunocompromised adults, including patients with acquired immunodeficiency syndrome.^{8,163,593,612} Respiratory tract infections have ranged from mild upper respiratory tract illnesses to pneumonia. In patients with acquired immunodeficiency syndrome, the pneumonia frequently is cavitory. Sinusitis and bronchitis also occur. An 11-year-old girl with cystic fibrosis had a *B. bronchiseptica* infection that might have been transmitted from a household cat.⁴⁶⁶ An adult patient who had received a kidney-pancreas transplant had pneumonia due to *B. bronchiseptica*.²⁰² The source of this infection might have been from recently vaccinated dogs. The patient’s dogs had received a live attenuated *B. bronchiseptica* intranasal vaccination.

Bordetella hinzii Infection

B. hinzii has occasionally been recovered from sputum cultures from patients with cystic fibrosis.^{195,516} The role of these isolates in pulmonary disease in cystic fibrosis is unknown. Some isolates likely represent transient colonization,⁵¹⁶ but one adult patient had the organism recovered during pulmonary exacerbations throughout a 3-year period.¹⁹⁵ *B. hinzii* can cause septicemia and cholangitis in adult patients with immunodeficiencies.^{20,135,193,279,296}

Bordetella holmesii Infection

In 1999, Yih and associates⁶¹⁷ reported the isolation of *B. holmesii* from the nasopharyngeal specimens of 33 patients suspected of having pertussis. Twenty-three of the cases were investigated further, and 19 (82%) of the patients were adolescents, 2 (9%) were adults, and 2 (9%) were children. All had cough: 61% had paroxysms, 26% had posttussive vomiting, and 9% had whoop. *B. holmesii* has been isolated from

nasopharyngeal specimens from patients with pertussis-like illnesses in France, Canada, and the Netherlands.^{399,428}

The incidence of pertussis-like illness due to *B. holmesii* is unknown. *B. holmesii* contains IS 481 and IS 1001. The two insertion sequence elements are routinely used to diagnose *B. pertussis* and *B. parapertussis*, respectively.^{15,123,343,428,546} If samples are positive for both IS 481 and IS1001, the illness is caused by *B. holmesii*. However, because infection with both *B. pertussis* and *B. parapertussis* can occur, dual positives can be *B. holmesii* or mixed infections with *B. pertussis* and *B. parapertussis*.¹²³ Use of *B. holmesii* specific primers has been advocated to avoid false interpretations.¹⁵

In Canada, Guthrie and associates²²⁴ developed a novel duplex real-time PCR assay for the detection of *B. holmesii*. The target in the PCR assay is a 50-bp segment of the *rec A* gene. They found that the prevalence of *B. holmesii* in Ontario was relatively low; of all swabs from patients with pertussis like illness, less than 1% were positive for *B. holmesii*.

B. holmesii has caused meningitis in a 12-year-old anorectic girl, bacteremia in four asplenic children, pneumonia in a 15-year-old child with relapsing nephrotic syndrome, and septic arthritis in a 15-year-old boy with chronic hemolytic anemia.^{161,398,444,561} This agent has also caused bacteremia in children with sickle cell disease.³⁶⁹

B. holmesii has been isolated from a 10-month-old boy with bacteremia and from patients with septicemia, endocarditis, and respiratory failure.^{138,404,541} In adults, *B. holmesii* has caused prosthetic valve endocarditis, pericarditis in a patient with lymphoma, and meningitis in an asplenic patient with systemic lupus erythematosus.^{292,341,418}

Bordetella trematum Infection

B. trematum has been isolated from chronic wounds, ear infections, and blood.^{7,146,531} All infections have been in adults with chronic vascular problems, impaired nasal function, and diabetes mellitus.

A 7-month-old infant with *B. trematum* bacteremia was described.⁴⁹¹ This child was developmentally delayed, malnourished, and anemic.

Bordetella ansorpii Infection

B. ansorpii was isolated from an infected epidermal cyst in a 19-year-old girl receiving anticancer chemotherapy.³⁰⁹

Bordetella petrii Infection

In adults, *Bordetella petrii* has been associated with suppurative mastoiditis, bronchiectasis, septic arthritis, and osteomyelitis and mandibular osteomyelitis.^{194,322,429,518} Long-lasting infection in an adult with bronchiectasis has been described.³²² *B. petrii* has been recovered from respiratory specimens of patients with cystic fibrosis.⁵¹⁶

Bordetella avium Infection

Bordetella avium is an avian pathogen, but it has been recovered from an adult with pneumonia. A *B. avium*-like strain was recovered from an adult with a 4-month history of productive cough.²³⁹

Klebsiella granulomatis

Mariam R. Chacko

Klebsiella granulomatis (formerly *Calymmatobacterium granulomatis*) is the causative organism for a chronic genital ulcer disease called granuloma inguinale or donovanosis, and it was first isolated in 1905 by Donovan in India.^{35,53} The organism is an encapsulated gram-negative rod measuring $1.5 \times 0.7 \mu\text{m}$, and for many decades, it was considered a unique species belonging to the subclass Proteobacteria.^{24,35,36} However, using DNA hybridization techniques and 16S rDNA sequencing, the organism was reclassified under the genus *Klebsiella*.³⁵

Transmission electron microscopy shows the organism has a complex cell envelope with an outer membrane, middle electron-opaque layer, and an inner plasma membrane. In addition to its regular bacterial structure (i.e., mesosome, ribosomes, and nuclear material), the cytoplasm contains electron-dense granules. The organisms are enclosed mainly in large histiocyte cells and occasionally in polymorphonuclear cells and plasma cells. They multiply intracellularly to approximately 30 organisms, eventually causing cell rupture.^{9,35}

EPIDEMIOLOGY

Granuloma inguinale occurs predominantly in young and older adults (20 to 40 years of age) and is a cause of endemic genital ulcerative disease in tropical and subtropical regions of the world today, including Papua New Guinea, South Africa, India, Brazil, and Australia.^{5,10,37,42,51} As with all genital ulcerative diseases, granuloma inguinale has been given greater attention as a risk factor for development of human immunodeficiency virus (HIV) infection. A rapid test for donovanosis was introduced in Durban, South Africa, in the early 1990s, which facilitated increased diagnosis of this disease in HIV and other sexually transmitted infections (STIs) initiatives in South Africa and Australia.^{5,16,33} In developed countries, case reports of granuloma inguinale emerged in the 1990s among immigrants living in metropolitan areas such as Toronto, Rome, and London.^{21,32,47} The most recent case report from Milan, Italy, was in 2012 of an 18-year-old, pregnant girl from Bolivia.²⁷

In the United States during the preantibiotic era, the estimated population prevalence of granuloma inguinale in the United States was 5000 to 10,000 cases,³⁵ with more than 1000 cases reported per year to the Centers for Disease Control and Prevention (CDC). Since the introduction of antibiotics, the prevalence of this disease has declined rapidly, with 75 cases reported in 1977 and 17 cases reported in 1982. No cases have been reported through standard surveillance reports by the CDC in recent years. However, case reports have been published: one case in 1985 in California¹⁹ and one case in 1991 in Texas.³¹ Cases from Chicago in 2006⁴⁵ and Charlottesville, Virginia, in 2009 and in 2012 have been reported.² Although the prevalence of the disease is

low, this disease needs to be suspected in North America and Europe because of international travel and immigration.

Granuloma inguinale is a rare occurrence in children. In the early 1950s, 4% of 1- to 4-year-old children in a Papua New Guinea population had granuloma inguinale. Although the mode of transmission in adolescents and adults is considered to be sexual, the mode of disease transmission in these children was thought to be by skin-to-skin contact from sitting on the laps of infected adults.³⁵ Cases published since 1997 report otitis media, ear polyps, mastoiditis, neck mass, cervical lymphadenopathy, and meningitis as the initial manifestations of donovanosis in infants and children.^{1,4,17,18,43} The modes of transmission in these cases were thought to be perinatal and by skin-to-skin contact.^{1,4,17,18,43}

The risk factors and mode of transmission of granuloma inguinale are not clear. It is considered a sexually transmitted disease. Coexistence of granuloma inguinale with other STIs occurs commonly. Syphilis has been described in as many as 23% of patients with granuloma inguinale. In one report, HIV-1 antibodies were found in as many as 8% of male patients with granuloma inguinale.^{31,42} O'Farrell and associates⁴¹ found that Zulu men and women with granuloma inguinale and secondary syphilis were more likely to have had sexual intercourse compared with those with other genital ulcer diseases. It is usually more common in males than in females, but among adolescents in Durban, South Africa, the disease occurred more commonly in girls than in boys, probably indicating sexual activity between adolescent girls and adult men.³⁴ Anal intercourse also has been associated with rectal and penile lesions of granuloma inguinale.²⁸ The disease has been diagnosed in 12% to 50% of marital or steady sexual partners.^{35,40} Studies from India and South Africa have reported a preponderance of granuloma inguinale cases among uncircumcised male patients with poor genital hygiene.^{34,35}

PATHOGENESIS AND PATHOLOGY

K. granulomatis organisms invade mononuclear endothelial cells. Extensive acanthosis and dense dermal infiltrates of mainly plasma cells and histiocytes have been observed in the indurated nodules, the initial clinical presentation of the disease. Polymorphonuclear cell infiltration also occurs, but lymphocytes are rare findings when secondary infection develops. The pathognomonic feature of granuloma inguinale is a large, infected mononuclear cell that is 25 to 90 μm in diameter and contains many intracytoplasmic cysts filled with deep-staining Donovan bodies. Metastatic spread to the bones, joints, liver, and lymphatics occasionally occurs.³⁵

A possible link between human leukocyte antigen B57 (HLA-B57) and granuloma inguinale infection may exist. Class I, class II, and DQ

antigens have been detected in the genital ulcers of individuals with granuloma inguinale.³⁸ Circulating lymphocytes and tissue-level lymphocyte subpopulations in granuloma inguinale have been studied.^{49,50} T-lymphocyte and B-lymphocyte infiltration in tissues is almost identical, without any significant difference in ulcerogranulomatous and hypertrophic variants of granuloma inguinale. Total leukocyte, absolute lymphocyte, and total T lymphocytes counts; CD4, CD8, and CD22 levels; and the CD4/CD8 ratio are all increased significantly in the ulcerogranulomatous variant of granuloma inguinale. In contrast, the hypertrophic variant causes a significant elevation only in the CD4/CD8 ratio. This finding suggests a greater cell-mediated immune response in the ulcerogranulomatous variant of granuloma inguinale and is consistent with the paucity of Donovan bodies in smears obtained from patients with this variant.^{50,49}

CLINICAL MANIFESTATIONS

The incubation period of granuloma inguinale usually is less than 2 weeks, but it can be as long as 3 months. The disease begins as one or more subcutaneous nodules that erode through the skin to produce clean, large, beefy-red, granulomatous ulcers that bleed easily. The lesions are sharply defined and painless, and the ulcers feel hard when palpated. The disease usually is limited to local tissue, and constitutional symptoms are therefore unlikely. Autoinoculation is a common manifestation that produces kissing lesions. The genitalia are involved in 90% of cases, the inguinal region in 10%, the anal region in 5% to 10%, and extragenital sites (usually involving the head and neck), in 1% to 5%. Regional (inguinal) lymphadenopathy is not associated with granuloma inguinale.

The morphology of the cutaneous lesions of granuloma inguinale can vary, depending on the stage of the disease. The exuberant or hypertrophic stage appears before secondary infection develops. It consists of large, vegetating masses with overgrowth of granulation tissue, usually in the perianal region. The ulcerative stage is accompanied by secondary infection. In this stage, large, spreading, shallow necrotic ulcers with a foul odor may be observed. The cicatricial stage results after prolonged healing and is characterized by fibrosis, scarring, depigmentation, keloid formation, elephantiasis, and stenosis of the vagina, urethra, and anus. Although lymphadenopathy is an unusual occurrence in granuloma inguinale, pseudobuboes and pseudoelephantiasis of the genitals (i.e., massive edema) may be seen. Pseudobuboes are the result of deep, inguinal granulomas; pseudoelephantiasis is caused by cutaneous extension of lesions and inflammation.^{13,31,35}

In male patients, lesions usually occur on the prepuce, coronal sulcus, and frenulum of the penis.^{10,35,36} Multiple sites of genital ulceration (i.e., vulva, vagina, and cervix) have been observed only in nonpregnant women (Fig. 130.1).^{2,13,34,36} The most common clinical manifestation in women is vulvar ulcerations in pregnant and nonpregnant women, followed by genital tract bleeding reported for nonpregnant women (20%).³ Extragenital sites may be involved in up to 6% of cases through hematogenous spread, and lesions are reported in the mouth, chin, axillae, abdomen, pelvic cavity, and foot.^{12,14,20,26,29,35,44,48,52} These distant sites usually are associated with a primary lesion in the genital area.³⁵ Lesions in the oral cavity have been described after apparently successful treatment of genital lesions.¹² Donovanosis ulcers may take longer to heal in HIV-positive individuals, and greater destruction of tissue may occur.^{20,35,36}

DIAGNOSIS

Granuloma inguinale usually is diagnosed clinically. In contrast to other genital ulcers, the ulcers are larger in granuloma inguinale, are painless, bleed easily in response to touch, and usually are not associated with inguinal lymphadenopathy.⁴⁶ The CDC STI surveillance case definition for granuloma inguinale of a confirmed case is a clinically compatible case that is laboratory confirmed.⁸

If donovanosis is suspected, a swab for this condition should be taken before swabs for other organisms to allow an adequate amount of cellular material to be obtained. Examination of appropriately stained specimens from active lesions remains the most reliable diagnostic test

FIG. 130.1 Granuloma inguinale.

FIG. 130.2 Donovan bodies.

using Wright-Giemsa or Warthin-Starry blue-black stain. A modified Giemsa stain (i.e., Rapi-Diff) can also yield rapid results in a busy clinic.³⁵ Dark-staining Donovan bodies in large, histiocytic cells on a stained crush specimen from the lesion are identified (Fig. 130.2). A biopsy specimen, preferably stained with Giemsa or silver, is recommended for very early, very sclerotic, or heavily superinfected specimens.^{23,39,35} Donovan bodies have been identified on Papanicolaou smears from the cervix.¹¹

Although *K. granulomatis* has been successfully isolated by culture in South Africa and Australia, this method is not used due to difficulties in isolating the organism.^{6,53} Polymerase chain reaction (PCR) techniques for *K. granulomatis* have been developed, and a genital ulcer disease multiplex PCR test has been developed in Australia.³⁵ No molecular tests for detection of *K. granulomatis* DNA have been cleared by the US Food and Drug Administration, but such an assay can be useful when undertaken by a laboratory that has conducted a Clinical Laboratories Improvement Amendments (CLIA) verification study.⁵³ A serologic test for granuloma inguinale using the indirect immunofluorescence was developed in the 1990s in South Africa and found to be highly sensitive but not specific.¹⁵

TREATMENT

Antibiotics with strong activity against *K. granulomatis* are those effective in the treatment of gram-negative bacilli or those whose lipid solubility ensures good intracellular penetration. The CDC recommends treatment of adolescents with 1 g of azithromycin taken orally weekly or 500 mg taken daily for at least 3 weeks until all lesions have completely healed.⁵³ Alternative regimens include 100 mg of doxycycline taken orally twice each day for at least 3 weeks, or 750 mg of ciprofloxacin taken orally twice each day for at least 3 weeks, or 500 mg of erythromycin base taken orally four times each day for at least 3 weeks, or one double-strength tablet (i.e., 160 mg/800 mg) of trimethoprim-sulfamethoxazole taken orally twice per day for at least 3 weeks. All of these regimens should be prescribed until all lesions have completely healed.⁵³ A clinical response to antibiotics should be noticed within a week of treatment; the lesions should become paler and less friable. After a week of treatment, the lesions become smaller, and total healing of the area takes 3 to 5 weeks.³⁵ Ceftriaxone is a possible treatment option for chronic, recurrent granuloma inguinale.³⁰

Pregnant and lactating adolescents should be treated with an azithromycin or erythromycin regimen, and consideration should be given to adding a parenteral aminoglycoside such as 1 mg/kg of gentamicin given intravenously every 8 hours. Doxycycline and trimethoprim-sulfamethoxazole are contraindicated during pregnancy.⁵³

The treatment regimen for an HIV-positive person is the same as for an HIV-negative person. Treatment can fail in patients with coexisting HIV infection and immunosuppression; in contrast to HIV-negative patients, the mean duration to complete ulcer healing in these patients is significantly longer (25.7 days vs. 16.8 days).²² More intensive and prolonged antibiotic therapy such as an aminoglycoside (e.g., 1 mg/kg of gentamicin given intravenously every 8 hours) may need to be added if improvement is not evident within a few days of treatment.

Treatment information for children with granuloma inguinale is limited and is not addressed in the current CDC treatment guidelines.⁵³ The American Academy of Pediatrics *Red Book* recommends for children younger than 8 years of age, 1 g of azithromycin once each week for at least 3 weeks until the lesions have healed, and for children 8 years of age or older, 100 mg of doxycycline taken orally twice each day for at least 3 weeks until the lesions have healed. Alternative medications include suspension forms of trimethoprim-sulfamethoxazole or erythromycin.²⁵

PROGNOSIS

Healing is complete in patients who seek treatment early in the course of the disease and who comply with their medication and follow-up

regimens.^{30,34} Relapse occurs in approximately 10% of cases, especially if use of the antibiotic is discontinued before the primary lesion has healed completely. Donovan bodies may reappear within 7 to 10 days.³⁵ Up to one third of patients are reported to recover completely without a recurrence after receiving daily doses of ceftriaxone for 7 to 10 days.^{30,34}

Complications of granuloma inguinale include pseudoelephantiasis, urethral stricture, and pelvic abscess, which may require surgery. Vulvectomy is reserved for infections that have not responded to antibiotic treatment or for patients with severe vulvar elephantiasis.^{13,35}

The severe, mutilating complications of granuloma inguinale are primarily a result of delayed treatment or poor compliance with medication. In Durban, South Africa, almost one half of the male patients had ulcerations for 1 to 6 months before they sought medical care, and 16% had ulcerations for 1 to 3 weeks. In contrast, approximately 25% of female patients had ulcerations for 1 to 6 months, and 50% had ulcerations for 1 to 3 weeks.³⁰ Delayed medical attention may be related to limited education, ignorance of STIs, absence of suitable medical facilities, or embarrassment in seeking treatment because of extensive genital lesions. Another complication is the acquisition of HIV infection, especially when patients with ulcerations that are left untreated for a prolonged period have sexual contact with an HIV-positive partner.^{30,35}

PREVENTION

Sexual partners of persons with the disease who have had sexual contact within 60 days before onset of symptoms should be traced, examined, and treated. However, the value of treating an asymptomatic partner has not been established.⁵³ Treatment of granuloma inguinale when the nodule first appears is associated with a benign course. Community-based eradication that targets men with granuloma inguinale in endemic areas should be implemented. Neonates whose mothers have granuloma inguinale should have their ears, umbilicus, and genitalia carefully cleansed and should be given a course of prophylactic antibiotics.⁴⁶

Programs should be aimed at early suspicion and identification of lesions, access to care, provision of early treatment, and prevention of severe complications. Teaching the importance of personal genital hygiene, such as instruction on simple retraction of the foreskin in men and cleansing the penis with soap and water, also is effective.^{34,35} The CDC and the US Public Health Service provide technical instructions on required examinations and standard treatment regimens to panels of physicians and consular officers evaluating the health of aliens applying for entry into the United States.⁷

Campylobacter jejuni is a frequent cause of enteritis and less often of extraintestinal infection in humans. Since it first was recognized as a common human pathogen in the 1970s, appreciation of this agent's importance as a cause of disease has increased steadily. *C. jejuni* is one of the most frequent bacterial causes of human enteritis in the United States, and it is a leading cause of bacterial foodborne diarrheal disease throughout the world.^{6,43} Immunoreactive complications may develop after infection.^{252,270}

Although they are not isolated as frequently as *C. jejuni* and *Campylobacter coli*, other *Campylobacter* spp. are gaining recognition as human pathogens. At least 25 species of *Campylobacter* have been identified.²⁰¹ *Campylobacter fetus*, a classic cause of perinatal infection, also is an infrequent cause of bacteremia in immunocompromised hosts. *Campylobacter upsaliensis*, *Campylobacter lari*, *Campylobacter hyointestinalis*, and *Campylobacter concisus* are associated primarily with diarrheal disease. Normal and immunosuppressed hosts are affected by these species. Other less common *Campylobacter* spp. have been isolated from blood or stool or involved in periodontal disease. The clinical spectrum of these organisms is expanding as the testing for them becomes more widely available.

HISTORY

The pathologic consequences of infection with *Campylobacter* were recognized first in 1909 from studies of abortions in sheep,²⁰⁶ although it might have been identified in 1886, when Theodore Escherich described nonculturable, spiral-shaped bacteria.²⁹⁸ A few years later, Smith³⁰⁶ reported their association with bovine abortion and gave them the name *Vibrio fetus*. Although never confirmed microbiologically, these organisms are thought to have been *C. fetus* according to current nomenclature.¹⁶⁹ In 1947, the sheep abortion-associated organism *V. fetus* was isolated from a blood culture from a pregnant woman who had an influenza-like illness and delivered a stillborn infant with a necrotic, infarcted placenta.

In 1957, King hypothesized that *V. fetus*-related organisms might be associated with human enteric disease.^{37,173} In addition to pregnancy, gastrectomy, tooth extraction, heart disease, diabetes, and cirrhosis were predisposing conditions in King's 1957 review of 15 patients with *V. fetus* bacteremia.¹⁷³ Butzler and colleagues³⁷ showed that bacteria similar to *V. fetus* were present in the stools of children with diarrhea. This observation was confirmed rapidly and repeatedly.^{24,39,107,304,324}

Major differences in biochemical activities, growth characteristics, and DNA base nucleotide content between true *Vibrio* and *V. fetus* led to the establishment of the new genus *Campylobacter* by Sebald and Vernon in 1967.³⁴⁷ The genome of a representative *C. jejuni* was published in 2000.²⁴⁸ Information gleaned from this and comparative analyses of additional isolates have markedly advanced knowledge of these agents.^{101,136}

Many reports describing new *Campylobacter* spp. were published in the 1980s and early 1990s. *C. upsaliensis* was reported to be a pathogen in dogs and humans in 1983 and 1985, respectively.^{248,283} *C. lari*, a common isolate from healthy seagulls, was found to be a cause of gastrointestinal and extraintestinal disease in humans.^{19,323} Originally identified in the intestines of swine with proliferative ileitis, *C. hyointestinalis* was reported first as a human pathogen in a homosexual man with proctitis.⁷⁹ The hydrogen-requiring *C. concisus*,³⁴¹ *C. rectus*,²⁶⁸ and *Campylobacter curvus*; *Campylobacter showae*; and *Campylobacter gracilis* have been associated with periodontal disease. *Campylobacter sputorum* has been identified in abscesses, in bacteremia,^{56,139} and gastroenteritis,²⁰¹ and *Campylobacter mucosalis* was reported in two children with diarrhea.⁸⁴ *Campylobacter ureolyticus*, initially known as *Bacteroides ureolyticus*, was first described

associated with genital tract infections and later found to be isolated from stools.^{34,89}

Once called *Campylobacter*-like organisms 1 and 2, *Helicobacter cinaedi* and *Helicobacter fennelliae* are now classified in the *Helicobacter* genus.²³⁷ These pathogens cause enteritis and proctocolitis in homosexual men and occasionally cause bacteremia.^{247,337} *Campylobacter*-like organism 3, which also was described as causing enterocolitis, was recently identified for the first time as a cause of bacteremia.²²⁷ Two former *Campylobacter* spp., *Arcobacter butzleri* and *Arcobacter cryaerophilus*, are associated with abortion and enteritis in cattle and pigs, in addition to bacteremia and diarrhea in humans.¹⁷²

ORGANISM

The *Campylobacter* genus belongs to the family Campylobacteraceae, the order Campylobacterales, the class Epsilonproteobacteria, and the phylum Proteobacteria. The genus *Campylobacter* consists of 34 species and 14 subspecies (<http://www.bacterio.cict.fr/c/campylobacter.html>); about one half of them cause disease in humans. *Campylobacter* is a Greek word meaning "curved rod."

Members of this genus are fastidious, non-spore forming gram-negative rods that are curved, S-shaped, or spiral (Fig. 131.1). They may vary in width from 0.2 to 0.9 μm and in length from 0.5 to 5.0 μm . Although most grow at 37°C (98.6°F), *C. jejuni* grows best in cultures maintained at 42°C (107.6°F). The thermophilic cluster of the genus *Campylobacter* includes *C. jejuni*, *C. coli*, *Campylobacter upsaliensis*, *Campylobacter insulaenigrae*, and *C. lari*. Most *Campylobacter* spp. require microaerophilic growth conditions (i.e., 5%–10% oxygen). *Campylobacter* spp. usually are motile, with a single polar flagellum or two flagella, one at each end of the rod. Exceptions include *C. gracilis*, which is nonmotile, and *C. showae*, which has multiple flagella. *Campylobacters* are oxidase positive and reduce nitrates but do not ferment or oxidize carbohydrates.²⁵⁰

Some species, including *C. sputorum*, *C. concisus*, *C. mucosalis*, *C. curvus*, *C. rectus*, and *C. hyointestinalis*, may require hydrogen for primary isolation and growth. Many media selective for isolation of *Campylobacter* spp. have been developed, but because of species differences in antibiotic resistance patterns, no single formulation allows isolation of all species

FIG. 131.1 Scanning electron microscopy of *Campylobacter jejuni* strain 20-01. (From Baqar S, Rice B. *Campylobacter jejuni* enteritis. *Clin Infect Dis.* 2001;33:901–5.)

TABLE 131.1 Growth and Biochemical Characteristics of Species of the Genus *Campylobacter*

<i>Campylobacter</i> Species	GROWTH							
	25°C	37°C	42°C	Anaerobic Conditions	In CO ₂ Inhibitor	Glycine 1%	Bile 1%	Charcoal Casein Deoxycholate
<i>C. lari</i>	–	+	+	+	+	+	+	+
<i>C. upsaliensis</i>	–	+	+	+	+	–	+	+
<i>C. fetus</i>	+	+	(–)	–	+	+	–	–
<i>C. hyointestinalis</i>	(+)	+ ^a	+	+	+	+	NA	NA
<i>C. concisus</i>	–	+	+	+	+	+	NA	NA
<i>C. mucosalis</i>	+	+	+	+	+	+	NA	NA
<i>C. sputorum</i> ^b	–	+	+	+	+	+	+	+

^aBest at 35°C (95°F).^b*C. sputorum* has three biovars with different biochemical characteristics.+, Positive; –, negative; (+), most strains positive; (–), most strains negative; H₂S, hydrogen sulfide gas; NA, data not available or found; R, resistant; S, susceptible; TSI, triple sugar iron agar.

of clinical importance.¹¹³ For example, *C. jejuni* and *C. coli* are resistant to cephalothin, whereas *C. fetus* is susceptible. A filtration method with nonselective media may be used to complement direct culture on selective media for the detection of antibiotic-susceptible *Campylobacter* spp. Because of their small size and motility, campylobacters may pass through filters with pores of 0.45 to 0.65 μm, whereas other enteric organisms are retained.³⁹

Although colonies may appear on plates within 24 to 48 hours, growth of campylobacters from stool may take as long as 72 to 96 hours. Primary isolation from blood may require 2 weeks.⁷ Gram stains of young cultures reveal vibrioid forms, and longer incubation may yield spherical or coccoid bodies. Colonies are not pigmented. *Campylobacter* spp. usually can be distinguished from one another on the basis of biochemical tests and growth characteristics (Table 131.1). Although the significant pathogens *C. jejuni*, *C. coli*, and *C. lari* cannot be discriminated reliably by the use of 16S rDNA data, these sequences provide a substantially improved basis for the identification and differentiation of *Campylobacter* spp.¹¹⁰ Many investigators have applied molecular techniques to identify enteric campylobacters directly from stool.

C. jejuni belongs to rRNA superfamily VI, a specialized subgroup of gram-negative bacteria that also includes *Arcobacter* and *Helicobacter*. The species *C. jejuni* has two subspecies, *C. jejuni jejuni* and *C. jejuni doylei*. *C. jejuni doylei* can be differentiated from *C. jejuni jejuni* by the failure of *C. jejuni doylei* to grow at 42°C (107.6°F), lack of nitrate reduction, and sensitivity to cephalothin. For brevity, we refer to *C. jejuni jejuni* as *C. jejuni*.

C. jejuni has a circular chromosome of 1.64 million base pairs (i.e., 30.6% guanosine and cytosine).²⁴⁶ Marked differences in pathogenic surrogates (i.e., motility, colonization of chicks, invasion, and translocation of cultured cells) are associated with variable chromosomal sequences in different passage sequences for a single isolate, and unique chromosomal sequences are associated with known pathogenic isolates of *C. jejuni*. Genomic analyses demonstrate that substantial differences exist among organisms classified by conventional means and that some of these differences are associated with the capacity to cause disease in humans.^{101,136,245} Genomic sequence analyses have yielded a catalog of phase-variable surface structures (including lipooligosaccharide and capsule) that appear to relate to pathogenesis and immunity,^{90,246} a lack of classical operon structure, repetitive DNA, and an unexpected capacity to produce polysaccharide.²⁴⁶ Populations of *C. jejuni* are nonclonal, and interstrain exchange of genetic material occurs.⁵⁶

EPIDEMIOLOGY

Human infection with *C. jejuni* occurs worldwide.²³ *C. jejuni* persists in zoonotic niches (Table 131.2), and most human infections are thought to arise from these reservoirs. Chickens and contaminated water are the main sources of campylobacteriosis in developed countries. The organism is a common commensal of the gastrointestinal tract of cattle, pigs, dogs, cats, and most birds used as human food,^{25,265} and transmission from these sources occurs. A meta-analysis showed a prevalence of

Campylobacter among petting zoo animals of 6.5% and a prevalence of 24.7% among household pets.²⁵⁷ Raw milk and unpasteurized milk products have also been incriminated in outbreaks of *Campylobacter* infections.

Freshwater bathing sites may yield *Campylobacter* organisms that are epidemiologically linked to human infections.^{235,292,293} Drinking water directly from a river, stream, or lake also increases the risk of *Campylobacter* infections¹⁹⁹ and waterborne outbreaks have been reported.¹⁶⁷

In the United States, *C. jejuni* infection peaks in late summer and early fall (Fig. 131.2). In a study from Philadelphia, June and July were shown to be the 2 months with the highest incidence of disease. A study from Switzerland reported peak incidence of *Campylobacter* cases during July and August over several years, with a shorter peak noted in December and January.²⁸⁹ Reports from Australia and Sweden also suggest increased number of campylobacteriosis cases in summer months.^{88,128} Dairy cows in the United Kingdom have higher concentrations of *Campylobacter* organisms in spring and autumn, but the concentration of *Campylobacter* organisms in beef cattle at slaughter does not change with season; as many as 90% of beef cattle may have stools positive for *Campylobacter*.³¹³ In subtropical areas, the peak incidence of isolation of *C. jejuni* often is associated with the rainy season. In most tropical climates, rates of isolation are similar throughout the year. Overall increases in temperature and humidity are associated with a higher risk of disease. Cooler river water was associated with a higher risk of disease. Lower water temperature has been associated with longer environmental persistence of *Campylobacter*.³⁵⁴

Studies of volunteers show an incubation period of 2 to 4 days after challenges ranging from 800 to 2 × 10⁹ colony-forming units.²² Fecal shedding of *C. jejuni* by humans may last a median of 2 to 3 weeks, with a range of 3 days to several months.^{39,169,240}

The distribution of *C. jejuni* infections within populations is linked to the level of industrialization. In industrialized countries, *C. jejuni* infection is often found in children and adults with enteritis and seldom in healthy individuals.³²¹ In less industrialized areas, *C. jejuni* is isolated frequently from children, even in the absence of enteritis (Tables 131.3 and 131.4). In industrialized countries, *C. jejuni* has been isolated from 1% to 13% of children with diarrhea, and the prevalence of infection among healthy individuals has been 0% to 1.5%.^{24,37,272,304}

A 5-year, laboratory-based national surveillance of *Campylobacter* spp. showed an isolation rate of 5.5 cases per 100,000 person-years (with *C. jejuni* accounting for 99% of the *Campylobacter* isolates) (Fig. 131.3).³²⁶ Population-based isolation rates of *Campylobacter* in the United States range from 28 to 1560 per 100,000 annually. In 2014, FoodNet identified 6486 cases of *Campylobacter* infection in 10 sites from the United States from a total of 19542 cases of foodborne infections, with an incidence of 13.45 cases per 100,000 people, which was higher than the rate reported for 2006 to 2008. The number of hospitalizations attributed to *Campylobacter* infection during that year was 1080 (17% of cases), and 11 deaths were reported (case-fatality rate of 0.2%).⁵³ The estimated rate of death attributable to *Campylobacter* in the United States is between 100 and 124 per year. The case-mortality rate is between 0.10% and 0.23%.¹³¹

NR, Not reported.

The World Health Organization (WHO) reported 92 million cases of *Campylobacter* infections globally in 2010 of 550 million cases of diarrheal illness. *Campylobacter* was only second in frequency to norovirus in causing foodborne diarrheal illness. *Campylobacter* resulted in 21,374 (95% confidence interval [CI], 14,604–32,584) deaths annually.¹²⁹ Almost 50% of cases of campylobacteriosis globally occurred in children younger than 5 years of age. Guillain-Barré syndrome (GBS) occurred in 31,700 (95% CI, 25,400–40,200) of campylobacteriosis cases.¹⁷⁴ A registry-based study demonstrated fivefold and twofold increases in mortality rates for the first 30 days or first year, respectively, after developing *Campylobacter* infection.¹³¹

A study from Botswana revealed isolation of *Campylobacter* from stools of children admitted to the hospital with diarrhea to be associated with longer hospital stay and higher mortality rates.²⁵⁴ A Canadian report showed a 5.1% hospitalization rate for *Campylobacter* infections between 2001 and 2004, with highest rates at extremes of age (<1 year and >59 years). A UK population-based study conducted in 2008 through 2009 showed that *Campylobacter* resulted in 0.5 million cases of intestinal infections yearly and was the most common bacterial pathogen to cause such an infection. The median estimated costs to patients and the health service for *Campylobacter* was £50 million (95% CI, £33m–£75m), the cost per case of *Campylobacter* infection was estimated to be £85, and

FIG. 131.3 Annual isolation rates of *Campylobacter* by age and sex in the United States, 1982–86. (From Tauxe RV, Hargrett-Bean N, Patton CM, et al. *Campylobacter* isolates in the United States, 1982–1986. *MMWR CDC Surveill Summ*. 1988;37:1–13.)

the cost of a GBS hospitalization related to *Campylobacter* was £1.26 million.³¹⁹

Population-based studies in England, the United States, and Sweden showed a bimodal age distribution, with a peak of illness occurring in children younger than 5 years and a second peak at 15 to 29 years of age.^{278,324} The highest isolation rate occurs in the first year of life (see Fig. 131.3). Reports from the United Kingdom suggest a decrease in incidence of campylobacteriosis in the younger age groups in more recent years compared with an increase in the population older than 60 years of age.¹⁰⁶ Similarly, most recent reports from Switzerland show an increase in overall cases of campylobacteriosis (about 150 cases per 100,000 people in 2012) with a decrease, however, in cases for those younger than 5 years of age.²⁸⁹ An increase in the number of campylobacteriosis has been seen in Norway.⁵¹ A report from Sydney, Australia showed that *Campylobacter* accounted for 22% of diarrheal episodes and was the most common cause of diarrhea in all age groups except in children younger than 5 years of age, for whom viruses were the leading cause of diarrhea.⁸⁸ A report on foodborne illnesses in Japan revealed an incidence rate of *Campylobacter* infection of 92.5 (95% CI, 55.2–154.5) per 100,000 people.¹⁸¹ Doubling of the quantity of chicken meat produced since 2000 may account for increasing numbers of reported campylobacteriosis in the industrialized world in recent years.³⁰³

A male predominance of campylobacteriosis is seen, which has been reproducible in an animal model, suggesting physiologic differences in response to infection between the genders.³¹⁷ In young adults (20–24 years old), however, it has been suggested that there is a female predominance in disease, which may result from higher contact and exposure of females in that age group to children.²⁸⁹

In industrialized regions, most sporadic cases occur because of handling, preparing, and consuming contaminated raw or undercooked poultry or beef.^{24,38,57,98,296,307,324} Raw milk and contaminated water are less common sources.^{141,148,210,327,352} Poor kitchen hygiene plays a role in transmission^{59,98}; the risk for acquiring infection is inversely related to the frequency of using soap to clean cutting boards.³²⁴ Barbecues represent a special hazard because they permit easy transfer of bacteria from raw meat to hands and other food and from there to the mouth.^{39,199} Other identified risk factors are eating at restaurants and takeaways.^{54,59,98} Increased number of chicken meals has been identified as a risk factor for sporadic infection with *Campylobacter* spp. in children.¹⁷ Eating fruits and vegetables has been found to be protective against the acquisition of campylobacteriosis.^{17,199}

Cases of *Campylobacter* infections in children have also been associated with contact with pets from the household or petting zoos.²⁵⁷ Contact with dogs and living on farms with livestock is a risk factor

for sporadic cases.¹⁹⁹ An estimated 17% of enteric illnesses due to *Campylobacter* in the United States result from contact with animals and their environment.¹²² Eating cantaloupe and queso fresco and Hispanic ethnicity have been identified as risk factors for sporadic *Campylobacter* infection in a study from Arizona.²⁵⁹ Current or recent use of proton pump inhibitors is associated with higher rates of campylobacteriosis in adults.³⁵⁹

Sporadic cases of *C. jejuni* infection occur much more frequently than outbreaks. Hospital outbreaks associated with food provided from the hospital kitchen have been reported.¹⁵⁸ A rural setting and higher income have been associated with higher numbers of infections.^{21,85}

Campylobacter has been reported as an important agent in bacterial travelers' diarrhea, mainly travelers returning from Asia.^{133,187,279} In a report from the FoodNet, 42% of enteric diseases related to travel were caused by *Campylobacter*; high numbers of cases were reported from Asia, South America, Central America, Europe, and Africa.¹⁷⁰ Outbreaks of *C. jejuni* infections in men having sex with men have been identified.¹⁰⁰ An outbreak due to inadequate milk pasteurization was reported in 2015.⁸¹

In less industrialized regions, *Campylobacter* is associated with childhood diarrhea in 8% to 45% of cases, but it is isolated at similar rates from healthy children.^{39,52,102} The highest rates of *Campylobacter* isolation are for children younger than 5 years of age.³⁹ As many as 75% of *Campylobacter* infections occurring during the first year of life are asymptomatic.⁵² The Global Enteric Multicenter Study (GEMS) looked at children 0 to 59 months old with diarrhea from centers in Africa and Asia and found that *Campylobacter* infections from the Asian centers only caused 6.6% to 16.1% of cases of diarrhea, depending on the center and age group.¹⁷⁹ In the Malnutrition and Enteric Disease (MAL-ED) study, which recruited 2145 children from eight sites in Africa, Asia, and South America, *Campylobacter* was the leading cause of diarrhea in the first and second years of life and was isolated from 30% to 40% of diarrheal stools and at a lower frequency from nondiarrheal stools.²⁵⁸

Usually, a contaminated food or a water vehicle transmits *Campylobacter*. However, direct transmission of the agent may occur, usually to individuals with direct exposure to reservoir animals or to those who process contaminated animal products.³⁴ Person-to-person spread may occur in areas of high contamination, such as where diapered children are present.²⁴⁹ In one study, increased number of children in the household and diaper use were associated with higher odds of occurrence of campylobacteriosis in children.¹⁷ Intrapartum transmission also has been documented.^{36,348} Asymptomatic mothers may transmit the infection to their newborns.³⁶

In developing countries, transmission is multifactorial. Free-roaming poultry, toddlers, unsafe water supply, and lack of adequate disposal of excreta are documented sources.¹¹¹ However, proving that *Campylobacter* causes disease in regions where the agent is environmentally pervasive is difficult. Confounders include statistically indistinguishable rates of isolation from diarrhea cases and matched controls (see Table 131.3), and direct evidence that the presence in a household of *Campylobacter* shared between humans and chickens is associated with protection from diarrhea. Improved knowledge of the immune responses that protect from *Campylobacter* infection and disease and knowledge of the components of *Campylobacter* required to cause disease are needed to understand the agent's epidemiology better.

Because of the biochemical inactivity of campylobacters, discriminating species and subspecies by conventional chemotaxonomic methods is problematic. The consequences of this difficulty include ambiguities in epidemiologic investigations and low resolution in studies of mechanisms of virulence and immunity. Effort is being invested in devising genotyping schemes.^{63,353}

Much needs to be learned about the epidemiology of *Campylobacter* spp. other than *C. jejuni* and *C. coli*, a group of organisms that made up only about 1% of *Campylobacter* spp. reported to the Centers for Disease Control and Prevention (CDC) from 1982 to 1986.³²⁴ These organisms are gaining ground as etiologic agents of undiagnosed gastroenteritis. Non-*jejuni*, non-*coli* *Campylobacter* spp. also have been associated with extraintestinal disease, especially bacteremia in patients with comorbidities affecting the immune system.

Age-specific isolation rates of *C. fetus* parallel those of *C. jejuni* and *C. coli*; rates peak in infancy and increase in young adulthood, and *C. fetus* increases substantially in elderly persons. Seasonal distribution patterns of *C. jejuni*, *C. coli*, and *C. fetus* are similar, with peaks occurring in warm months. In a surveillance study, *C. jejuni* and *C. coli* isolates were predominantly from stool, whereas 54% of *C. fetus* isolates with a known source were from blood.³²⁴ The epidemiology and antimicrobial susceptibilities of 111 *C. fetus* strains isolated from 103 patients from 1983 to 2000 in Quebec, Canada, were determined.³³⁹ The isolation site was blood in 69% of the patients, stool in 20%, and other body fluids, including fluid surrounding the aorta, bile, synovial fluid, cerebrospinal fluid, tubo-ovarian abscess, ascites, and pleural fluid, in 11% of these patients.³³⁹

C. fetus, an important cause of sporadic abortion in cattle and sheep, may be isolated from the intestines and genital tracts of these animals.²⁵⁰ Contaminated food and water are the suspected sources of infection for sheep, cattle, and other animals, including goats, pigs, cats, dogs, hamsters, guinea pigs, antelopes, chickens, and turkeys.⁹²

C. fetus bacteremia usually occurs in immunosuppressed hosts (especially elderly men), pregnant women, and neonates^{272,335}; however, cases in immunocompetent hosts have been reported.^{212,226} Predisposing conditions include alcoholism or cirrhosis, diabetes mellitus, heart disease, malignancy, splenectomy, and corticosteroid or other immunosuppressive therapy.^{65,150,277} *C. fetus* is not considered a major cause of gastroenteritis, perhaps because of the failure of this organism to grow in stool specimens evaluated by routine laboratory methods for *C. jejuni* and *C. coli*.^{250,324} In addition to raw milk,³⁵⁵ raw beef liver³¹⁰ and nutritional therapy (i.e., raw fruit, vegetable juice, calves' liver, coffee enemas) are associated with *C. fetus* infection.⁴²

First associated with human disease in a homosexual man with proctitis, *C. hyointestinalis* (from *hyos* meaning "hog" and *intestinalis* meaning "pertaining to the intestines") originally was isolated from the intestines of swine with proliferative ileitis.^{79,250} *C. hyointestinalis* also has been isolated from the stool of persons with nonbloody, watery diarrhea.⁷⁰

C. lari is frequently isolated from apparently healthy seagulls, although seagulls do not play a direct role in its epidemiology.³²⁵ Epidemiologically and microbiologically similar to *C. jejuni*, *C. lari* has been reported to cause enteritis in patients with and without a history of animal exposure and bacteremia in two elderly patients with multiple myeloma and permanent pacemakers.^{1,218,225,301,325} A waterborne outbreak of *C. lari*-associated gastroenteritis also has been reported.³⁰

The *C. upsaliensis* group is associated with gastroenteritis, breast abscess, spontaneous abortion, and bacteremia in normal hosts and

with opportunistic infections in immunocompromised persons.^{119,123,248} Conditions predisposing to *C. upsaliensis* bacteremia include gallbladder surgery, ectopic pregnancy, kwashiorkor, and acquired immunodeficiency syndrome (AIDS).²⁴⁸ Young puppies and kittens are potential transmitters of *C. upsaliensis*.¹²¹ In one study *C. upsaliensis* accounted for 77% of *Campylobacter* species isolated from fecal swabs of dogs. An outbreak in a childcare center suggested direct transmission between humans.^{108,161}

C. concisus has been implicated in gastrointestinal disease. In contrast to *C. jejuni*, disease distribution occurred throughout the year rather than at certain seasons. Patients most commonly affected were children younger than 1 year of age and elderly people. *C. concisus* has been isolated from oral flora of 3-year-old children and found to be part of the oral microbiota protective against caries.¹⁹⁵

PATHOLOGY

Most *C. jejuni* infections are not associated with illness or notable pathologic features. When illness does occur, watery diarrhea, invasive enteritis, or systemic infection may result. The spectrum of pathology reflects this range of manifestations. Acute watery diarrhea may occur in the absence of grossly visible pathologic features. Acute inflammation of the colon and rectum is the hallmark of *C. jejuni* invasive enteritis,²⁰⁰ although hemorrhagic jejunitis and ileitis may also occur.^{68,74,169}

In patients who have undergone proctoscopy, normal mucosa is found in approximately 50%; in the remainder, mucosal edema, congestion, friability, and granularity are seen. The spectrum of histologic changes ranges includes minimal edema with acute and chronic inflammatory cells and no vascular congestion, moderate inflammation and cryptitis, and crypt abscess formation. Acute appendicitis, mesenteric lymphadenitis, and ileocolitis have been reported in patients who have undergone appendectomies while they were infected with *C. jejuni*.²²

At low concentrations of *C. jejuni* organisms, infection is a precursor to immunoreactive complications in which disease results from immunologic effectors generated in response to infection that damages neurons. After adjustments for comorbidities, the demonstration that *Campylobacter* infection is associated with increased mortality rates over the course of a 1-year period after infection suggests that unidentified severe late disease occurs.¹³¹

C. jejuni is one of a few microbes that have been hypothesized to trigger a common mechanism leading to lymphomas.¹¹⁶ *C. jejuni* has also been associated with cases of immunoproliferative small intestinal disease, alone or in conjunction with other microbial overgrowth.^{76,211}

PATHOGENESIS

The mechanisms by which *C. jejuni* causes diarrhea, dysentery, and less frequently, systemic disease are not well understood. Campylobacters invade different cell lines. Motility, adherence, and invasion of cells and ability to produce toxins have been associated with the capacity to cause disease,^{12,13,94,96,132,166,201,217} but the pattern of their expression in disease-associated isolates is not uniform. Dogs,²⁶⁴ rhesus macaque (*Macaca mulatta*),⁸⁶ rabbits,³¹² mice,⁸⁶ and hamsters¹⁴⁷ have been evaluated as models of *Campylobacter* enteritis, but none faithfully reproduces the disease seen in humans. A mouse intranasal challenge model¹⁶ has been developed for use in studies of *C. jejuni* invasiveness, and a ferret model¹⁸ has been developed for studies of *C. jejuni*-induced diarrhea. Studies in mice mainly have served as disease models associated with *Campylobacter* spp.²⁰¹ As few as 500 to 800 colony-forming units have the potential to cause disease.¹⁵⁷

Capsular polysaccharides produced by *C. jejuni* increase adherence to human intestinal epithelia (i.e., jejunum, ileum, and colon) and provide resistance against some epithelial antimicrobial peptides, including β -defensin and lysozyme. The structural diversity of outer membrane lipooligosaccharides is an important virulence factor of *C. jejuni*. Sialylated lipooligosaccharides have been associated with more severe gastroenteritis and development of GBS.¹⁴³ Flagella help overcome peristalsis and allow entry into the mucous layer. Secreted flagellar and nonflagellar proteins are required for adhesion and invasion. Absence of flagellin A (flaA) has been associated with decreased motility and virulence.

Cytolethal distending toxin (CDT) is the best-characterized toxin associated with *Campylobacter*. CDT has three subunits: CdtA and CdtC play a role in binding to host cells and allowing delivery of CdtB, which has a DNase I-like activity and plays a role in host cell cycle arrest and apoptosis leading to disruption of the mucosal barrier. Type IV and VI secretion systems are associated with various *Campylobacter* species. *C. fetus* and *C. rectus* have a surface layer that makes them more resistant to lysis and phagocytosis than other *Campylobacter* spp. In addition to *cdt*, other genes that confer virulence to *Campylobacter* include those that encode the *Campylobacter* invasion protein (*ciaB*), *Campylobacter* adhesin to fibronectin F (*cadF*), and heat survival and stress response proteins (*htrB* and *clpP*).¹⁰³

Survival of *Campylobacter* spp. is facilitated by the ability to form biofilms.¹⁵¹ Formation of mixed bacteria biofilms may be one strategy for *Campylobacter* to escape host immunity or cause asymptomatic intestinal colonization.¹⁵¹ *Campylobacter* also relies on other bacteria for iron uptake because its growth depends on iron uptake, but it is not able to produce its own siderophores.¹⁵¹ In vitro studies demonstrate a capacity to disrupt tight junctions of intestinal epithelial cell monolayers and preferentially induce proinflammatory cytokine responses through activation of nuclear factor- κ B (NF- κ B) and production of interleukin-18 (IL-18). These capacities and the demonstrated microtubule-dependent eukaryotic cell evasion mechanism¹⁷⁷ may contribute to establishment and maintenance of *C. jejuni* in the gut.⁴⁶

Campylobacter induces an inflammatory cascade and results in activation of innate immunity and recruitment of T and B lymphocytes and neutrophils. Matrix metalloproteinase-2 (MMP-2) plays a role in mediating the immunopathogenesis of *C. jejuni* in mice.⁹ Another murine model showed that *Campylobacter* induced phosphatidylinositol 3-kinase to play an important role in neutrophil recruitment and intestinal inflammation. *C. jejuni* GD1a-like sialylated glycan interacts with macrophage sialoadhesins and promotes a proinflammatory and type I interferon (IFN) response. Sialylated lipooligosaccharides also stimulate type I IFN production by dendritic cells and promote B-cell responses through CD14-dependent production of IFN- β and tumor necrosis factor- α (TNF- α).¹⁴³ *Campylobacter* also induces production of IL-1 β through activation of the NLRP3 inflammasome without a cytotoxic effect.²⁹

Susceptibility of different *Campylobacter* strains to the bactericidal effects of normal human sera may dictate which strains are more likely to manifest with bacteremia. For example, *C. concisus* is very sensitive to such effects, whereas *C. fetus* is resistant.¹⁷⁴

IMMUNITY

The preponderance of evidence of protective acquired immune responses to *C. jejuni* comes from studies of children in developing countries. These children have more frequent symptomatic infections at younger ages; with increasing age, the rate of symptomatic infection decreases. The number of *C. jejuni* organisms excreted per gram of stool of infected individuals also declines with increasing age,³²⁸ as does the duration of excretion of the organism.³²⁶

These phenomena parallel increasing titers of *Campylobacter*-specific antibodies.^{25,26,163,203,318,328,332} Serum *Campylobacter* immunoglobulin A (IgA) and IgM increase within a week of the infection and disappear within 2 to 3 months, whereas IgG levels increase several weeks after infection and last significantly longer.¹³⁰ Specific IgA can be isolated from the stools of infected subjects. Additional evidence for the effect of antibodies is provided by breast-feeding, which is associated with a reduced frequency of *C. jejuni* diarrhea.^{281,336} Adult volunteers who became ill after a first challenge were protected from illness after a repeat challenge with a homologous strain,²² and resistance was related to the presence of anti-*Campylobacter* antibodies.

A study challenging adult volunteers with *C. jejuni* CG8421 reported lack of immunity after the first challenge and development of symptomatic infection with a second challenge, suggesting that immunity to *Campylobacter* depends on the strain and repeated exposure.¹⁷⁵ A Canadian study showed recurrence rate of *C. jejuni* infection within 5 years after an initial infection to be 1.2%, suggesting that immunity against *C. jejuni*, at least in developed countries where the environmental

load of *Campylobacter* may not be very high, is not persistent or sufficient to protect from subsequent infections.¹¹

Prolonged, severe, and sometimes recurrent infections occur in immunodeficient patients.^{204,207} Hypogammaglobulinemic patients have difficulty clearing *Campylobacter* organisms. Patients with late-stage AIDS are at increased risk for severe relapsing *Campylobacter* infection; patients with early stages of human immunodeficiency virus (HIV) infection and high CD4 counts are not at risk.

Immunity to disease may not protect against asymptomatic colonization. The bacterial components against which the protective immune responses are directed are unknown, although several potential immunogenic antigens and virulence factors have been investigated.²³² The sum of this evidence forms the basis for attempts to develop *C. jejuni* vaccines.

Very little information is available on cellular immune responses to *C. jejuni*. Cellular responses may play an important role in facilitating the formation of antibody and in clearing intracellular *C. jejuni* from eukaryotic cells.¹⁵⁷

An in vitro organ culture model system using human gut showed that microcolonies of *C. jejuni* adhere more frequently to small intestine tissue than to colon tissue, despite similar cytokine responses in the tissues. Significant increase in production of interferon- γ (IFN- γ) and IL-22 was noticed in the presence of *C. jejuni* along with IL-23 and to a lesser extent IL-17 production, inferring the presence of an innate and adaptive helper T lymphocyte type 1 and 17 (Th1/Th17) immune response to *C. jejuni*. Findings from the use of mice models suggested that innate immunity and nitric oxide production play important roles in response to *C. jejuni* infection.³²¹

Despite the mass of evidence indicating protective roles for immune responses, the *Campylobacter* components against which protective immune responses are targeted are unknown. Similarly, attempts to relate classic serotyping schemes, flagellar types, or presence or absence of virulence factors with disease-causing capacity have yielded associations of poor strength. The completion of the genome sequence of *C. jejuni* (NCTC 11168) in 2000²⁴⁶ enabled studies to be pursued that are beginning to explain the relationships between bacterial components and immune responses. The *Campylobacter* glycome is remarkably plastic,¹⁶⁸ and *Campylobacter* spp. produce a surprising variety of carbohydrates (i.e., about 8% of the genome is dedicated to the biosynthesis of surface carbohydrates). Multiple mechanisms exist for sequence variation for genes encoding the glycome. In a clinical trial, researchers demonstrated that passage of *C. jejuni* in volunteers could be associated with phase variation in lipooligosaccharides.²⁶³

CLINICAL MANIFESTATIONS

C. jejuni produces a spectrum of manifestations, the most common of which is enteritis. Bacteremia, other systemic manifestations, and perinatal infections occur infrequently.

Enteritis

Children with *Campylobacter* enteritis may have unformed stools, watery diarrhea, inflammatory diarrhea, or a combination of these manifestations.^{7,24,39,169,240,304} Inflammatory diarrhea can be so severe that it is misdiagnosed as inflammatory bowel disease.³⁰⁴ Inflammatory diarrhea is a more common occurrence in industrialized countries, and secretory watery diarrhea more typically occurs in developing areas. Patients developing diarrhea abroad tend to keep the presentation that is common in their country of origin.³⁶⁵ Patients with ciprofloxacin-resistant strains have a longer duration of diarrhea than patients infected with sensitive strains,²³¹ although a study from Finland shows opposite results.⁸⁰

Most cases of enteric illness subside within 7 days, but 20% to 30% last for 2 weeks, and 5% to 10% may persist longer, with a relapsing course lasting for weeks.^{169,240} In one third to one half of patients, the initial symptoms are periumbilical cramping, intense abdominal pain, malaise, myalgia, and headache. An acute abdomen or appendicitis may be suspected at first⁴⁵ because acute abdominal pain occasionally may be the only initial symptom; pseudoappendicitis or mesenteric adenitis and terminal ileitis can be found.²⁵³ The pain may be mild and intermittent for several weeks, and vomiting is a common occurrence.

Secretory diarrhea with 10 or more profuse, watery stools per day may occur. Because this course commonly occurs in younger children, dehydration frequently (10%) is an outcome. Relapse of symptoms may occur.

The symptoms of inflammatory diarrhea are similar to those caused by *Shigella*, invasive *Escherichia coli*, and *Salmonella* and consist of generalized malaise, fever, abdominal cramps, tenesmus, bloody stools, and fecal leukocytes seen on light microscopy.²⁰⁰ Fever without other symptoms may develop and can be associated with febrile seizures.³⁵⁸ Toxic megacolon with massive bleeding may occur.^{114,164,290} In neonates, blood-streaked formed stools or hematochezia may be associated with the isolation of *C. jejuni*.^{114,164} The abdomen is tender, especially in the right lower quadrant. Splenomegaly occurs rarely.

C. upsaliensis and *C. concisus* are the two most common emerging campylobacters to cause gastroenteritis, although reported cases of gastroenteritis associated with *C. fetus*, *C. hyointestinalis*, *C. insulaenigrae*, *C. lari*, *C. mucosalis*, *C. sputorum*, and *C. ureolyticus* exist.²⁰¹ These emerging *Campylobacter* spp. may have an important role in gastroenteritis without an identifiable cause. In a study from Ireland, *C. fetus* accounted for 2.4% of cases of intestinal campylobacteriosis.

C. upsaliensis was the only organism isolated from 83 patients in a large stool culture survey using a filtration system for *Campylobacter* in Belgium.¹⁰⁸ Ninety-two percent of patients had acute-onset diarrhea. Vomiting (14%) and fever (7%) were uncommon and symptoms usually abated in less than a week. Gross or occult blood was identified in 25% of cases, and neutrophils were seen on fecal smear in approximately 20%. Erythromycin (11 patients) or amoxicillin (2 patients) eradicated the organism, with resolution of symptoms in all 13 patients treated with antibiotics.¹⁰⁸ An Australian study identified *C. upsaliensis* in 19 (0.1%) of 18,516 stool specimens from August 1992 to March 1999 at the Royal Children's Hospital in Melbourne.¹⁶¹ Infection with *C. upsaliensis* was associated with milder disease than infection with *C. jejuni*; patients with *C. upsaliensis* infection had significantly less fever, diarrhea, and rectal bleeding.

C. concisus has been associated with gastroenteritis in children. In an older study, *C. concisus* was isolated from 13.2% of stools of 174 children with diarrhea compared with 9% of 958 children without gastrointestinal manifestations.²⁰¹ A later study from Denmark showed *C. concisus* to be the second most common bacterial isolate from stools of 8302 patients studied, and the annual incidence was reported to be 35 cases per 100,000 inhabitants. In this study, healthy controls did not have *C. concisus* in their stools, which contradicts previous studies that questioned the true pathologic role of *C. concisus*, especially in children. Four genomospecies of *C. concisus* exist that may have different virulence and clinical manifestations.^{189,233}

Six clinical *C. lari* isolates were referred to the national *Campylobacter* reference laboratory at the CDC in 1982 and 1983.³²⁵ Clinical illness associated with these isolates included enteritis in four patients, severe crampy abdominal pain in a 7-year-old girl, and terminal bacteremia in a 71-year-old man with multiple myeloma and chronic renal failure. The ages of the four patients with enteritis were 8 months, 3 years, 22 years, and 39 years. Diarrhea was watery or mucoid, and fever was an unusual occurrence. Potential exposure included consuming chicken, having contact with house pets, drinking untreated surface water, and eating raw oysters. *C. lari* colitis also developed in an HIV-infected woman.⁷⁵

C. hyointestinalis has been isolated from the stool specimens of adult and pediatric patients experiencing nonbloody, watery diarrhea⁷⁰ and a rectal culture from a homosexual man with proctitis.⁷⁹ Over a 4-year period, 20 strains of *C. curvus* were isolated from two separate and distinct clinical settings, a hospital survey of infectious causes of bloody diarrhea, and an outbreak of Brainerd (chronic) diarrhea in northern California.¹

A study from Ireland was the first to report isolation of *C. ureolyticus* from diarrheal stools; the organism accounted for 23.8% of 349 stool samples that were positive for *Campylobacter*. Of eight patients who were followed clinically, only two were children (1 and 6 years of age). All eight patients presented with abdominal cramping and had symptoms of more than 5 days' duration. Three of the patients were immunosuppressed; two were diabetic, and one had HIV-associated lymphoma.³⁴

Extraintestinal Infections

Bacteremia with *C. jejuni* occurs much less commonly than enteritis. Bacteremia was recognized first in malnourished children, patients with chronic illness or immunodeficiency, and patients at the extremes of age.^{4,115,207,269} Cirrhosis, cancer, immunosuppressive therapy, and HIV infection commonly are underlying conditions in patients with bacteremia.²⁵⁶ These findings led to the view that *C. jejuni* bacteremia was a disease of relatively immunocompromised patients. However, most *C. jejuni* blood isolates are from healthy individuals who often have histories of recent gastrointestinal disease.³⁰⁵

The average incidence of *Campylobacter* bacteremia in England and Wales is 1.5 cases per 1000 intestinal *Campylobacter* infections. The CDC reports that only 0.4% of *C. jejuni* isolates in the United States are obtained from blood cultures.³²⁴

Most *C. jejuni* strains are susceptible to killing by serum, a finding that perhaps explains the transient nature of the bacteremia and its tendency to resolve without specific therapy. In HIV-infected patients, *Campylobacter* bacteremia occurs more frequently and with increased morbidity and higher mortality rates,^{202,256,329} although these numbers have improved with combined antiretroviral therapy. Fatal cases have been reported in the absence of enteric disease.²⁰²

In a Danish study reporting 46 cases of *Campylobacter* bacteremia over a 10-year period, the incidence of bacteremia was estimated at 2.9 cases per 1 million person-years. Only one case was reported for a child. Patients with bacteremia tended to be older than patients with isolated enteritis, and enteritis was detected in 59% of patients with bacteremia. *C. jejuni* accounted for 37 cases; *C. coli*, *C. fetus*, and *C. lari* were responsible for the rest. The mortality rate associated with bacteremia was 4%. Patients who survived had no recurrence within a 365-day follow-up period.

A study from Spain reported an incidence of 4.7 cases per 1 million person-years over a 23-year period (i.e., 71 episodes of bacteremia). Of these events, 31% originated extraintestinally, and 26% were primary infections. Isolates included *C. jejuni* (66%), *C. coli* (19%), and *C. lari* (12%). The mortality rate was 16.4%. The recurrence rate was 5%. In the Danish and Spanish studies, patients had comorbidities, including major gastrointestinal surgeries, alcoholism, HIV, immunodeficiency, and malignancy.⁸²

In the largest published series on *Campylobacter* bacteremia, 183 episodes were reported from France from 178 patients in a 5-year period. Only seven patients were younger than 15 years of age. Fever was the only presenting symptom in 42% of cases. *C. fetus* accounted for 57% of cases. Other isolated *Campylobacter* spp. included *C. jejuni*, *C. coli*, and *C. lari*.²³⁸ *C. fetus* is the most common *Campylobacter* leading to bacteremia.³⁴⁹ Bacteremia is one of the most common manifestations of uncommon *Campylobacter* species (Table 131.5).

Increased recognition of extraintestinal *Campylobacter* infections has resulted from the growing application of appropriate microbiologic culture methods. The incidence of *C. jejuni* bacteremia probably remains underestimated. Typically, blood cultures are not performed for individuals with a primary complaint of diarrhea. Rarely, cholecystitis,^{118,262} urinary tract infection,⁵⁵ pancreatitis,⁹⁷ hepatitis,¹⁷⁸ splenic abscess,²⁹⁵ osteomyelitis, myocarditis,^{224,243} myositis,⁹⁵ and meningitis^{65,332} can result from *Campylobacter* infection. A case report of *C. jejuni* prosthetic joint infection in an older man was reported.³⁴⁵

C. fetus is the non-*jejuni*, non-*coli* *Campylobacter* species that most commonly causes disease in humans. It causes perinatal disease but is otherwise rare in healthy children. More commonly, it can cause bacteremia in adults with other comorbidities, especially immune suppression. Typically, illness begins with fever, malaise, and headache. Chills and night sweats are prominent, as is weight loss in prolonged illness. Diarrhea, nausea, vomiting, and abdominal pain occur in as many as 38% of cases, and hepatosplenomegaly or jaundice develops in two thirds.^{115,360} Pulmonary involvement is a rare finding.^{27,115} *C. fetus* also has a tropism for the vessels.

Three patterns of invasive *C. fetus* disease have been described.²⁷⁷ Clinical manifestations of the first localized infection accompanied by septicemia include meningitis,^{32,193,344} endocarditis,^{78,271} pericarditis,²¹⁹ thrombophlebitis,⁴⁰ mycotic aneurysm,^{77,277} cellulitis,^{40,91} gluteal abscess,⁶¹

TABLE 131.5 Clinical Features Associated With Extraintestinal Infection by Atypical *Campylobacter* Species

Campylobacter Species	Extraintestinal Clinical Features
<i>C. fetus</i>	Bacteremia, sepsis, meningitis, vascular infections, septic abortion, spondylitis
<i>C. upsaliensis</i>	Bacteremia, abscesses, abortion, hemolytic uremic syndrome
<i>C. lari</i>	Bacteremia
<i>C. hyointestinalis</i>	Bacteremia
<i>C. sputorum</i>	Pulmonary, perianal, groin, knee, and axillary abscesses, bacteremia
<i>C. concisus</i>	Periodontitis, brain abscess, bacteremia
<i>C. curvus</i>	Liver abscess, bronchial abscess, bacteremia
<i>C. gracilis</i>	Periodontitis, brain abscess, head and neck infection, fatal bacteremia
<i>C. rectus</i>	Periodontitis, necrotizing soft tissue infections, empyema thoracis, vertebral abscess
<i>C. showae</i>	Intraorbital abscess, bacteremia, cholangitis
<i>C. ureolyticus</i>	Oral and perianal abscesses, soft tissue and bone infections
<i>C. insulaenigrae</i>	Bacteremia
<i>C. hominis</i>	Bacteremia
<i>C. rectus</i>	Bacteremia, skin infections, vertebral, septic cavernous sinus thrombosis
<i>C. volucris</i>	Bacteremia

septic arthritis,¹⁸⁵ salpingitis,³² spondylitis^{44,48} and peritonitis.^{120,322} The second form is transient, asymptomatic bacteremia, which may be self-limited.^{115,272,276} Prolonged and recurrent bacteremia, with waxing and waning symptoms as spontaneous relapses and remissions occur, is the third pattern of invasive *C. fetus* infection.^{27,50,155,360}

C. curvus has been associated with polymicrobial liver and lung abscesses in two patients with cancer. *C. rectus* was reported in a polymicrobial breast abscess in a patient with lymphoma.¹ *C. concisus*, *C. curvus*, *C. gracilis*, *C. lari*, *C. mucosalis*, *C. rectus*, *C. showae*, *C. sputorum*, and *C. ureolyticus* can be isolated from the oral cavity. *C. rectus* and *C. gracilis* are thought to be associated with periodontitis.²⁰¹ Fatal cases of bacteremia with *C. upsaliensis* and *C. gracilis* have been reported.^{228,297} *Campylobacter volucris* bacteremia was reported for the first time in an immunocompromised patient.¹⁸⁶ The extraintestinal clinical features of uncommon *Campylobacter* spp. are presented in Table 131.5.

Perinatal Infections

Occasionally, abortion or stillbirth, premature labor, neonatal sepsis, and meningitis caused by *C. jejuni* have been described, although these manifestations have been more commonly associated with *C. fetus*.²⁵¹ *Campylobacter*-associated second-trimester abortion usually is preceded by mild gastroenteritis.^{221,300} The placenta may have areas of necrosis, infarction, microabscesses, and inflammation. The most likely route of placental or fetal infection is through the bloodstream, although a case with possible ascending spread has been reported.⁶⁰ Maternal blood, placenta, cervix, vaginal, and stool cultures have yielded *C. fetus* in reported perinatal cases.^{193,300,357}

Infected infants often are premature. Illness in neonates typically is mild or asymptomatic, but symptomatic gastroenteritis and asymptomatic bloody diarrhea caused by *C. jejuni* have been reported in newborn infants.^{33,240} Bacteremia and meningitis also may occur.^{109,332,340} Hemorrhagic infarction, necrosis, and cystic degeneration of the cerebral cortex

are the cerebral lesions most commonly reported in *Campylobacter* meningitis.³⁵⁷ A case of second-trimester intrauterine growth restriction associated with *C. coli* has been described,¹⁸² and *C. curvus* has been incriminated in a premature birth.²⁰⁸ The source of the organism usually is the mother, who may be symptomatic or asymptomatic at the time of delivery.^{33,299}

Immunoreactive and Other Complications

An episode of *C. jejuni* infection may be followed by immunoreactive complications such as GBS,^{126,127,214,273} Reiter syndrome,^{162,261} reactive arthritis,^{69,262,286} and erythema nodosum.^{10,93,311,312} A preceding *C. jejuni* infection was documented by serologic methods or stool culture in 12% to 60% of patients with GBS.^{6,126,127,142,214} *C. jejuni* infection is the most commonly identified causal factor for GBS.²⁷⁰ However, the risk for development of this syndrome after having a *C. jejuni* infection is less than 1%.⁶ *Campylobacter*-associated GBS is associated with axonal degeneration and poorer outcome than in GBS associated with other causes.²⁷⁰

During the 2 months after a symptomatic episode of *C. jejuni* infection, the likelihood of GBS is approximately 100 times (30.4 cases/100,000 people) higher than the risk in the general population (0.3 cases/100,000 people).²⁰⁵ In a nested case-control study conducted from 1991 to 2001 using data from the United Kingdom General Practice Research Database, 20% of GBS cases were associated with *Campylobacter*.³¹⁹ A case-control study from India found that 27.7% of patients with GBS had evidence of a recent *Campylobacter* infection.¹⁶⁵ A study from Bangladesh showed higher rates of *Campylobacter* infection preceding GBS with positive serology in 57% of cases. Patients with *Campylobacter* infection were more likely to have an axonal variant, greater disability, and higher mortality rates; they also had higher titers of antibodies to gangliosides GM₁ and CD1a.¹⁵³

GBS appears to be an age-related risk. One study found no cases among patients younger than 20 years of age, 14 cases per 100,000 patients 20 to 59 years of age, and 248 cases per 100,000 infections in those older than 60 years of age.²⁰⁵ Certain serotypes of *C. jejuni* (e.g., O:19) are associated more frequently with the subsequent development of GBS.^{8,183} A study from Pakistan identified the *wlaN* gene in *C. jejuni* that encodes β-1,3-galactosyl transferase, which converts the GM₂-like lipooligosaccharide structure to a GM₁-like structure that is associated with development of GBS.²³⁴

The molecular mimicry between GM₁ ganglioside and *C. jejuni* lipooligosaccharide is one of the triggers of GBS.³⁶³ A positive correlation of serologic evidence of *C. jejuni* and antibody to GM₁ has been described.^{112,156} Lipopolysaccharide extracted from *C. jejuni* had a core oligosaccharide resembling the human ganglioside GM₁. Pure motor neuropathy with a tendency for more distal weakness and sparing of the cranial nerves have been associated with *C. jejuni* infection in patients with anti-GM₁ antibody.⁵

Campylobacter carrying the *cst-II* sialy transferase gene is associated with the development of GBS and Fisher syndrome, and gene polymorphisms may determine which syndrome develops after having *C. jejuni* enteritis.³⁶³ Cases of Miller-Fisher syndrome, a polyneuritis variant characterized by ophthalmoplegia, areflexia, and cerebellar ataxia, and Bickerstaff brainstem encephalitis, a Miller-Fisher variant with impaired consciousness, also have been associated with *C. jejuni* infection.^{117,149} These patients often have antibodies to ganglioside Q_{1b} (GQ_{1b}), which may be helpful in confirming the diagnosis.¹¹⁷ Chaperone molecules (i.e., human peripheral nerve heat shock proteins [HSPs]) have high sequence homology with components of *Campylobacter*, suggesting their potential involvement in the development of autoimmunity in the setting of GBS.¹⁹⁷

Reactive arthritis may be associated with *Campylobacter* enteritis, especially in adults with human leukocyte antigen-B27 (HLA-B27).^{69,286} *Campylobacter*-reactive arthritis can occur in 1% to 5% of patients infected.²⁶² The arthritis starts a few days to several weeks after an episode of diarrhea. Involvement of joints can be monarticular or multiple and migratory, and the large and small joints can be affected. Synovial fluid is sterile, and fever and leukocytosis are absent. The duration ranges from 1 week to several months, the course is self-limited, and the prognosis is good.¹²⁴ A study from Oregon that included 6379

culture-confirmed *Campylobacter*, *Salmonella*, *Yersinia*, *Shigella*, and *E. coli* O157 infections showed an incidence of 2.1 cases of reactive arthritis per 100,000 patients after *Campylobacter* infection. Women, adults, and patients with more severe illness were at higher risk for this complication. No association with HLA-B27 was found.³³⁸

C. jejuni and other campylobacters may be associated with the development of inflammatory bowel disease (IBD) in children, although Jess and colleagues¹⁶⁰ attribute increased rates of *Campylobacter* infections around the first episode of IBD to a possible detection bias. In one study, *C. concisus* was isolated from 65% (35 of 54) of stools from children with Crohn disease, and 12 other samples were positive for other non-*jejuni* *Campylobacter* (i.e., *C. rectus*, *C. gracilis*, and *C. showae*).²⁰¹ A study looking at bacterial DNA in the mucosa and lymph nodes of patients with Crohn disease found *Campylobacter* to be uncommon in that patient population, whereas *E. coli* was more commonly detected. However, a metaanalysis looking at the role of *Helicobacter* and *Campylobacter* species in IBD found *Campylobacter* species (specifically *C. concisus* and *C. showae*) to be associated with an increased risk of IBD.⁴¹

It has been postulated that *Campylobacter* enteritis can cause functional gastrointestinal disorders in children, including irritable bowel syndrome and dyspepsia.²⁸⁴ Moreover, *Campylobacter* has been associated with the development of Barrett esophagus. A study investigating 1753 cases of gastroenteritis, including 738 cases of *Campylobacter*, found that infection with *Campylobacter* increased the risk of celiac disease.²⁷⁵

Severe, persistent, and relapsing *C. jejuni* infections have been reported in patients with immune deficiencies, including congenital and acquired hypogammaglobulinemia and malnutrition.^{4,140,207} Patients with AIDS have increased frequency and severity of *C. jejuni* infections; the severity correlates inversely with the CD4 count.¹⁹⁴

A report from Peru showed that symptomatic and asymptomatic campylobacteriosis was associated with decreased weight gain by children (0–6 years of age) over the 3 months after infection. Severe episodes of symptomatic infection were associated with a significant decrease in linear growth over the 9 months after infection.¹⁹²

DIAGNOSIS

The initial characteristics of *C. jejuni* enteritis are not sufficiently distinctive to permit the diagnosis to be established on clinical grounds. The differential diagnosis includes *Shigella*, *Salmonella*, invasive *E. coli*, *E. coli* O157:H7, *Yersinia enterocolitica*, *Aeromonas*, *Vibrio parahaemolyticus*, amebiasis, and pseudomembranous colitis caused by *Clostridium difficile*. Fecal leukocytes are found in as many as 75% of cases of *Campylobacter* enteritis; gross or occult fecal blood is identified in 50%.^{22,24,200} White blood cell counts usually are normal, although a shift to the left in the differential count can indicate a high number of immature white blood cells. Mild elevations in alanine aminotransferase and alkaline phosphatase levels and the sedimentation rate are observed in as many as 25% of patients. *C. jejuni* intestinal infection has been suggested as a cause of thrombocytopenia, leukopenia, or pancytopenia.^{1,266,287}

Methods for demonstrating *C. jejuni* include direct microscopy,^{241,244} bacteriologic culture, antigen detection by electroimmunoassay (EIA) or enzyme-linked immunosorbent assay (ELISA),^{135,288,334} DNA probes,³³⁰ polymerase chain reaction (PCR),^{156,190,343} and serology. A rapid immunochromatographic assay received US Food and Drug Administration (FDA) approval in 2009. ELISA using recombinant P18 and P39 as antigens has demonstrated 91.9% sensitivity and 99% specificity.²⁸⁸ However, those results have not been consistent across studies.

The CDC 2015 definition of a confirmed case of campylobacteriosis relies on a positive culture, whereas culture-independent detection tests (CIDTs) support only the diagnosis of a probable case. Culture on selective media and incubation at 42°C under microaerobic conditions for 72 hours is the traditional gold standard for the diagnosis of *Campylobacter* infection. PCR enables some culture-negative *Campylobacter* infections to be diagnosed.^{190,191} In a prospective, multicenter study comparing four *Campylobacter* culture-selective media, four commercially available antigen detection CIDTs, and PCR, the sensitivity, specificity, and positive predictive value of antigen CIDTs were 79.6%

to 87.6%, 95% to 99.5%, and 41.3% to 84.3%, respectively. Of 209 samples that tested positive by at least one CIDT, only one was positive by all antigen CIDTs.⁸⁷ In the same study, a combination of two culture media for *Campylobacter*—cefoperazone, vancomycin, and amphotericin B (CVA) agar and modified charcoal, cefoperazone, and deoxycholate (CCD) agar—resulted in a higher yield of culture results. Serologic tests appear useful for epidemiologic investigations but are not recommended for routine diagnosis.

C. jejuni can be detected by darkfield and phase-contrast examination of fresh suspensions of stool. The distinguishing characteristic of *Campylobacter* is darting motility. Gram stain of stool showing *Vibrio* forms is useful for making a presumptive diagnosis.²⁸⁵ Using the direct carbol-fuchsin Gram stain method, Wang and Murdoch³⁵¹ reported 89% sensitivity and 99.7% specificity when examining stool samples of *Campylobacter*-infected patients. The indirect fluorescent antibody test can be used for identification of *Campylobacter* on smears, but standardized reagents for this procedure are not available from commercial sources.

Establishing a definitive diagnosis of *Campylobacter* infection requires demonstration of the organism in stool or in a tissue sample. Unfortunately, not all laboratories culture for *Campylobacter*, despite its frequency, and not all laboratories use the same culture technique.²¹³ Culture of *Campylobacter* from stool requires special methods and media. It can be accomplished with media that contain antibiotics⁷² to which *Campylobacter* organisms are resistant. If culturing is done on a medium free of antibiotics, diluted stool samples should be passed through a cellulose acetate membrane filter with a pore size of 0.65 µm to reduce the number of other enteric microorganisms.⁷² Inoculated plates should be incubated in 5% oxygen and 10% carbon dioxide at 37°C to 42°C (98.6°F–107.6°F). Colony formation may not be grossly visible until 72 hours after plating. Identification of colonies as *C. jejuni* or *coli* is based on a Gram stain showing characteristic morphology and positive catalase and oxidase reactions. Hydrolysis of hippurate establishes an isolate that meets the conventional inclusion criteria for *C. jejuni*.

Routine media usually are adequate for isolation of *Campylobacter* from normally sterile body fluids and tissues. There are no specific media for culture from blood samples, and not many studies have investigated isolation of *Campylobacter* species from blood using automated blood culture systems. However, *C. jejuni* may take more than the standard 5-day period to grow from a routine blood culture.¹⁹⁸

PCR analysis performed on fixed, routinely processed colon biopsies is an excellent diagnostic method for detecting *Campylobacter* from focal active colitis cases. An advantage of the PCR on tissue samples is that it can be done retrospectively from the paraffin block.²⁹¹ Multiplex PCR assays for detection of multiple diarrheogenic agents, including *Campylobacter*, have been studied and show promising results. In one study, positive agreement between the assay and culture or EIA for *Campylobacter* was 97%.¹⁷⁶ Another study suggested the benefit of such assays in detecting *Campylobacter* 5 days or more after onset of symptoms, when cultures may be negative.²⁵⁵

TREATMENT

Azithromycin is considered the drug of choice in adults and children.^{67,184} Most patients with *C. jejuni* enteritis have mild symptoms and do not require antibiotic therapy. For these patients, oral rehydration and replacement of electrolytes are sufficient. Patients who may benefit from antibiotic therapy have extraintestinal infections, fever, bloody stools, and symptoms lasting longer than a week.⁷ Patients with HIV infection or other immunodeficiency syndromes should be treated.

Most *C. jejuni* organisms are susceptible to macrolides, aminoglycosides, fluoroquinolones, chloramphenicol, imipenem, and clindamycin and are resistant to cephalosporins, tetracyclines, rifampin, penicillins, trimethoprim, and vancomycin.^{302,342} However, resistance to macrolides is starting to emerge, and cases have been reported worldwide.¹⁰⁴ Patterns of antibiotic resistance by *C. jejuni* show regional differences. In the past, quinolones were used as empiric therapy for adult traveler's diarrhea because of their good microbiologic activity against *Campylobacter*, *Shigella*, and *Salmonella* strains.^{6,66} However, since the late 1980s, *Campylobacter* strains have become increasingly resistant to

TABLE 131.6 Antibiotic Resistance Pattern of *Campylobacter jejuni* Isolates

Location and Reference	Study Years	No. Tested	PERCENTAGE OF ISOLATES RESISTANT TO THE DRUG

fluoroquinolones worldwide, except in Australia (Table 131.6). A UK study looking at samples collected between 1994 and 2014 showed an increase in fluoroquinolones resistance from 12.8% to 49.9% of isolates, whereas macrolide resistance was steadily low.³¹⁶

The emergence of fluoroquinolone resistance has been associated with the use of quinolones such as sarafloxacin, difloxacin, and enrofloxacin in veterinary medicine in Europe and the United States.^{73,146} The association of human infection with fluoroquinolone-resistant *Campylobacter* spp. and consumption of poultry prompted the FDA to withdraw enrofloxacin for use in poultry, effective September 2005.²³⁰ Despite this measure, it will take time for fluoroquinolone-sensitive *Campylobacter* spp. to be reestablished in the environment. A study comparing infection with erythromycin-resistant and erythromycin-susceptible isolates in children did not show any clinical difference in the course of disease or clinical presentation.

Although fluoroquinolone-resistant *Campylobacter* is thought to cause more severe disease, recent studies show opposite results. A study from Chile showed *C. jejuni* strains from animal and human samples to be more susceptible to antimicrobials than *C. coli* strains, but they exhibited a higher number of virulence genes.¹⁸⁸ Other positive and negative interactions between virulence genes and resistance to ciprofloxacin and erythromycin have been described.¹⁰³

Fluoroquinolone resistance in *C. jejuni* infections appears to be related to mutations in the genes encoding subunits of DNA gyrase, especially *gyrA*.¹³⁹ Resistance to tetracycline is mediated through the *tetO* gene. The frequency of erythromycin-resistant *Campylobacter* isolates is low (see Table 131.6). Macrolide resistance is induced by mutations in 23S rRNA genes. *Campylobacter* possess three copies of those genes; mutation of two copies results in macrolide resistance.²³⁶

A study from Iran looked at 30 food samples and 15 clinical samples of *Campylobacter*. The results showed high resistance to imipenem (86.49% of isolates).¹⁵

Whole-genome sequencing of two multidrug-resistant *C. coli* strains isolated from poultry in Colombia showed genes that encode proteins conferring antimicrobial resistance to aminoglycosides (Aph3'-III), lincosamides (InuC), fluoroquinolones (GyrA and GyrB), and tetracyclines (EF-G and TetO); genes that encode efflux pump components (CmeA, CmeB, TolC, MATE, MFS, MacA, MacB, RND, AcrB, and OM); and genes affecting CmeA-BCR operon regulation, which is associated with increased multidrug resistance.²⁰ A U.S. study looking at gentamicin-resistant isolates from humans and chicken meat described nine variants of gentamicin resistance genes. Human isolates were more genetically

diverse and displayed more resistance: 98.7% were resistant to tetracycline, 58.2% were resistant to quinolones, and 45.6% were resistant to macrolides.³⁶⁴

Data on antibiotic treatment are controversial. A meta-analysis of the effects of antibiotic treatment on duration of symptoms caused by *Campylobacter* spp. looked at 11 randomized, controlled trials. It concluded that antibiotic therapy (with erythromycin, ciprofloxacin, or norfloxacin) shortened the duration of intestinal symptoms by less than 2 days, especially if the drugs were given early in the course of disease.³³¹ Antibiotic therapy shortened the excretion of *Campylobacter* spp. from feces.³³¹ There are concerns about antimicrobial resistance and alteration of the intestinal microbiome that may predispose to chronic intestinal inflammation, especially with self-medication by travelers. However, antimicrobial therapy may be more important than previously thought for children because *Campylobacter* infection may stunt weight gain and linear growth in the months after infection. All immunocompromised and bacteremic patients with *C. jejuni* infections should be treated with an appropriate antibiotic such as gentamicin, imipenem, or both drugs.

Synergistic combination therapy is indicated for patients with meningitis and endocarditis, for which bactericidal activity is critical.²¹⁶ Patients with *Campylobacter* in their stool who are being treated for an extraintestinal *Campylobacter* infection with gentamicin should be prescribed supplemental oral therapy because gentamicin is ineffective against *Campylobacter* in the gut.⁷ Carbapenems are essential for treatment of meningitis, and prolonged courses of treatment up to 6 weeks have been suggested for these infections.³⁴⁴

Prolonged antimicrobial therapy and follow-up blood cultures are warranted for patients with *C. fetus* bacteremia because of the relapsing nature of the illness.²¹⁹ Chloramphenicol should be used with caution in treating *C. fetus* meningitis because clinical outcomes and in vitro susceptibility results for this drug have been disappointing.^{193,216}

PREVENTION

Tactics for prevention of campylobacteriosis include breast-feeding and avoidance of raw food and food that has been cooked under conditions that permit the survival of bacteria or that has been handled in such a way that bacterial contamination can occur. Risks for foodborne illnesses, including campylobacteriosis transmitted by restaurant-prepared meals, may be reduced by mandating that food-service employees obtain training in food safety, such as handwashing with soap and water after

handling raw poultry or meat, cooking poultry to 82°C (180°F) or until meat is no longer pink and juices run clear, and separating raw poultry from other foods during preparation.

A 24-month (2002–04), population-based, surveillance case-control study by FoodNet in the United States evaluated infants with laboratory-confirmed *Campylobacter* infection and identified risk factors associated with their infection. Identified risk factors include drinking well water, eating fruits and vegetables prepared at home, having a pet with diarrhea in the home, visiting or living on a farm, riding in a shopping cart next to meat or poultry, and traveling outside the United States.⁹⁶ Prevention measures should then be targeted at the potential source. Selected microorganisms may displace *Campylobacter* from its ecologic niches. This finding may prove useful in reducing *Campylobacter* contamination of food animals.^{215,222}

Attempts to develop vaccines against campylobacteriosis continue. A recombinant protein vaccine and a killed whole-cell and flagellin subunit recombinant vaccine have failed phase II trials. A capsule-conjugate vaccine that demonstrated efficacy against diarrheal disease in nonhuman primates is in phase I human trials, and a DNA vaccine is in the preclinical stage of development.²⁷⁴ The next step is to develop combination vaccines targeting different diarrheal agents.³⁴⁶

Tularemia

132

Gordon E. Schutze

Tularemia is an acute febrile illness caused by *Francisella tularensis*. Although it is primarily a disease of animals, humans also are highly susceptible hosts.

HISTORY

McCoy¹⁰¹ published the first documented evidence of tularemia in 1911, when he described a plague-like disease in ground squirrels (*Citellus beecheyi*) that occurred in Tulare County, California. Within 2 years, McCoy and Chapin¹⁰² isolated and characterized the organism *Bacterium tularensis* from naturally infected ground squirrels. They detailed the pathologic process produced in ground squirrels, defined the susceptibility of other animal species to *B. tularensis*, and identified fleas as vectors for the plague-like disease in 1912.

The first description of tularemia in humans was provided by Homma Soken, a court physician in eastern Japan. In 1837, he described an illness as “hare meat poisoning.” Almost a century later, Vail¹⁴⁴ and Wherry and Lamb¹⁵² independently reported the first etiologically proved case of tularemia in humans in 1914. Thereafter, knowledge of the organism, susceptible hosts, modes of transmission, and clinical manifestations of disease was acquired rapidly, and retrospective information was assessed in light of this new information.

Much of the current understanding of the disease in humans originated from the work of Edward Francis,^{52,53} a US Public Health Service surgeon. Intrigued by the new diseases, which were called “deer fly fever” by Pearse¹⁰⁹ in 1911 and “plague-like disease” by McCoy,¹⁰¹ Francis relocated to Utah in 1919 and established his laboratory in an unused coal shed.^{52,53,54,55,56} He soon recognized the singular cause of these two diseases and renamed them *tularemia* because of isolation of *B. tularensis*

from blood. He isolated the organism from humans and jackrabbits⁵² and demonstrated transmission of the organism by the deer fly.⁵⁴

A more complete historical review was provided in the classic paper by Edward Francis,⁵³ “A Summary of the Present Knowledge of Tularemia.” Almost 9 decades later, this article remains accurate and contains most of the knowledge essential for understanding tularemia.

ETIOLOGY

The causative agent of tularemia is *F. tularensis*, named in honor of Edward Francis. *F. tularensis* is a small (0.2 to 1.0×1 to $3 \mu\text{m}$), nonmotile, non-spore-forming, pleomorphic, gram-negative coccobacillus. It is a strict anaerobe that infects as a facultative intracellular bacterium.

Electron microscopic studies confirmed the presence of a delicate, almost transparent cell wall and the presence of pili on the surface of the organism. Wild strains of *F. tularensis* have a lipid-rich capsule with neither toxic nor immunogenic properties, although capsule loss has been associated with decreased virulence.

The outstanding growth characteristic of these fastidious organisms is their requirement for cysteine or sulfhydryl compounds in amounts exceeding those usually present in nutrient media. Although *F. tularensis* grows best on cysteine-glucose-blood agar and on coagulated egg yolk medium and less well in thioglycolate broth, it can be isolated in routine cultures and on enriched chocolate agar.⁸⁹ Hornick⁶⁸ suggested that the addition of cycloheximide and penicillin facilitates isolation of the organism from the respiratory tract or skin ulcers. In a study by Johansson and colleagues,⁷⁵ an Amies agar medium with charcoal and a Thayer-Martin medium with antibiotics were equal in preserving bacterial viability for 1 week, in contrast to saline or Stuart medium.

F. tularensis is killed readily by heat. Exposure to a temperature of 56°C (132.8°F) for 10 minutes is sufficient for killing. The organisms are not destroyed by freezing and may remain viable in frozen animal carcasses for as long as 3 years. However, adequate cooking renders the meat of game birds and animals harmless. Treatment with tricresol solution (1%) for 2 minutes also kills organisms in tissue; organisms from cultures are killed in 24 hours by 0.1% formalin.

Despite serologic homogeneity, four distinct subspecies of tularemia have been identified. *F. tularensis* subsp. *tularensis* (type A) accounts for approximately 90% of organisms isolated in North America and has been seen in Europe, whereas the less virulent subsp. *holarctica* (type B) is found primarily in Europe and Asia.^{18,83} These two strains can coexist in the same ecosystem.⁹⁹ *F. tularensis* subsp. *mediasiatica* has been isolated primarily in central Asian republics of the former Soviet Union.¹⁰⁸ *Francisella novicida*, which is isolated rarely and can be found worldwide, is the fourth subspecies, but this designation is not accepted by all.⁷⁷

Through the use of molecular typing techniques, type A isolates can be divided into two distinct clades, A1 and A2.¹³⁰ These clades have been further subdivided (i.e., A1a, A1b, A2a, and A2b) based on data from pulsed-field gel electrophoresis and global single-nucleotide polymorphism analysis.^{83,87,108} No differences have been found between infections caused by A2a and A2b; therefore, only three type A genotypes (i.e., A1a, A1b, and A2) appear to be clinically important. A1 isolates are mainly found in the eastern United States, and A2 strains occur in the western United States. Infections with A1b have significantly higher mortality rates than do infections from A1a, A2, or B.⁸⁷

F. tularensis can survive and replicate within antigen-presenting cells such as macrophages or dendritic cells, correlating with the organism's high level of virulence. The organism also can invade human erythrocytes, which may shield the pathogen from antimicrobials.⁶⁹ *F. tularensis* does not produce any exotoxin, but pharmacologic tests indicate that the organism contains a lipopolysaccharide (LPS) similar to that of gram-negative bacilli. Unlike LPS of other gram-negative enteric organisms, the LPS of *F. tularensis* is 1000-fold less potent and does not activate macrophages or endothelial cells to release proinflammatory cytokines through toll-like receptors.^{3,119,137,148} The O antigens of the major subspecies *F. tularensis* that are pathogenic to humans are identical in their carbohydrate content and structure, a finding implying that the differences in virulence among subspecies probably is not the result of the O antigen.^{116,141,147,149}

An electron-dense surface material resembling a capsule has been demonstrated with electron microscopy. This capsule-like complex is not always visible, suggesting it may be upregulated under specific conditions.⁷

EPIDEMIOLOGY

Tularemia has been reported throughout the United States, in East Asia, and in Europe.^{18,83,97,140,153} *F. tularensis* has been found in Canada and Mexico but has not been reported in South America or Africa. In the United States, the disease most commonly occurs in the south central region. From 2001 to 2010, three states (Arkansas, Missouri, and Oklahoma) accounted for approximately 40% of all reported cases (Fig. 132.1).²¹

In the United States, the incidence of tularemia has been recorded since 1927. Data from a highly endemic region found an average annual incidence of 0.4 cases per 100,000 people.²⁰ The number of human cases declined steadily from 1939 (2291 cases) until 1975 (129 cases). Since then, the number of reported cases of tularemia has remained consistent, with a range between 90 and 310 cases annually.²² This range probably is a gross underestimate of the actual incidence. In 1968, in a serologic survey of 1936 subjects in California, approximately 1% of this population had antibody against *F. tularensis*.⁴⁴ Using skin test antigens, Casper and Phillip¹⁹ showed that 6.6% of 365 people in eastern Montana had evidence of previous infection with *F. tularensis*. Of those for whom skin test results were positive, 80% had no previous history of the disease, a finding indicating a high number of subclinical or self-limited infections. The number of deaths of humans infected with tularemia ranges from 0 to 4 per year.²²

FIG. 132.1 Reported cases of tularemia in the United States, 2001–10. One dot is placed randomly within the county of residence for each reported case. Cases were reported from 47 states. Six states accounted for 59% of reported cases: Missouri (19%), Arkansas (13%), Oklahoma (9%), Massachusetts (7%), South Dakota (5%), and Kansas (5%). (From Centers for Disease Control and Prevention [CDC]. *MMWR Morb Mortal Wkly Rep.* 2013;62:963–6.)

Persons especially at risk are hunters, trappers, meat processors, muskrat farmers,¹⁵⁵ cooks, lawn mowers and brush cutters,⁴⁸ sheep herders and shearers,⁷⁴ and laboratory workers.^{125,145} The incidence of tularemia among American Indians and Native Alaskans (0.3 deaths per 100,000) is significantly higher than that among whites (0.04) and African Americans (<0.01), and in all age groups, boys and men have a higher incidence of tularemia than girls and women.²¹

From 2001 to 2010, the average annual incidence of tularemia ranged from approximately 0.05 to 0.07 cases per 100,000 boys (0.01 to 0.06 cases per 100,000 girls) 0 to 14 years of age, with the highest incidence occurring among boys 5 to 9 years of age. Adults older than 75 years of age have an incidence of tularemia higher than that of children.²¹ Children acquire tularemia by the same routes as adults: vector bites, animal bites, and ingestion of infected, inadequately cooked meat.

Tularemia occurs throughout the year, but peaks occur in the summer and winter months, depending on the region. May through August accounted for 77% of all cases of tularemia onset from 2001 to 2010.²¹ Tularemia occurs more commonly in the central and southern states during the summer months, when ticks are more prevalent. The incidence in the northern and eastern states peaks in the winter months during the hunting season.

The most common sources of human infection are contact with infected animals or their carcasses and bites by ticks or tabanid flies (i.e., deer flies). Less commonly, people acquire the disease from the bite of a diseased animal or one in which the mouth has been contaminated by the ingestion of a diseased animal. Numerous outbreaks of human tularemia have occurred by water transmission in water contaminated by voles, beavers, lemmings, and muskrats.^{10,23,73,80,90} Infection also may occur by aerosolization of the organisms, especially in laboratory workers,^{81,145} lawn mowers and brush cutters,⁴⁸ farm workers (i.e., inhalation of dust and threshing material contaminated by voles and other rodents),^{36,67} and those cleaning infected animals.⁶⁴ Person-to-person transmission has not been documented.

Hopla,⁶⁷ in describing the ecology of tularemia, states that “rarely does one encounter a zoonotic disease of such complexity.” To understand the development of epizootics and transmission to humans, the role of numerous vertebrates (i.e., humans and wild and domestic animals) and many invertebrates must be considered.

Approximately 100 species of wild mammals, nine species of domestic animals, 25 species of birds, and several species of fish and amphibians can be infected naturally,¹⁰⁷ but probably fewer than a dozen species of mammals are important in the transmission of *F. tularensis*.⁶⁷ Lagomorphs (i.e., rabbits and hares) and some rodents (i.e., muskrats and voles) are

highly susceptible to *F. tularensis*. Sheep and domestic rabbits are also susceptible but have low sensitivity to the organism, particularly in areas where *F. tularensis* is endemic.⁸⁸ Domestic dogs and cats can also transmit disease to humans after contact with an infected animal or tick bite.^{93,118,156}

Vertebrate animals are called *reservoirs*, but they rarely are true reservoirs because most of them become sick and die or recover, with elimination of the organism. The varying hare (i.e., snowshoe rabbit) is less susceptible to *F. tularensis* and may serve as a reservoir because of its high natural resistance and carrier state.⁵¹ Protozoa, which serve as reservoirs for many other intracellular pathogens, may do the same for *F. tularensis*.¹

Many invertebrates can be infected experimentally by *F. tularensis*, but relatively few are infected naturally. In 1924, ticks were first described as vectors for *F. tularensis* infection in guinea pigs. However, the role of ticks in the spread of the human disease was not recognized until 1949, when Washburn and Tuohy¹⁵⁰ reported that 56% (391 of 704) of tularemia cases in Arkansas were associated with exposure to ticks. Ticks remain the most common vectors for *F. tularensis* in the United States.

At least 13 species of ticks are infected naturally by *F. tularensis*.^{67,153} The main species involved in transmission to humans are *Dermacentor andersoni* (wood tick), *Dermacentor variabilis* (dog tick), and *Amblyomma americanum* (Lone Star tick). A fourth tick, *Haemaphysalis leporispalustris* (rabbit tick) does not transmit tularemia directly to humans, but it perpetuates the cycle of infection by acting as the sylvatic vector between rabbits.

When the tick feeds on an infected animal, the organisms penetrate the gut into the hemolymph and are disseminated throughout the body, including the salivary glands. The tick then transmits the organisms by injecting them with saliva when it feeds on another animal. Transmission by tick fecal contamination also is likely. Ticks, biting flies (i.e., deer flies), and fleas probably are responsible for the continuing endemic disease in susceptible animals and for epizootic disease.¹⁶ Infrequently, mosquitoes and mites may transport *F. tularensis* mechanically from animal to animal or from animal to human.^{67,153} Humans act as terminal hosts of *F. tularensis* because they do not transmit it to other humans or to other mammals.

A few cases of tularemia acquired by cat bite have been reported.^{5,17,88,93,150,156} Because cats rarely are infected by *F. tularensis*, transmission may be the result of mechanical transmission from the contaminated teeth or claws of a cat that has come into contact with or has fed on an infected animal. Cat bites may be an important source of disease in children.

Ecogenetic analysis of *F. tularensis* in North America shows that the subspecies have specific geographic distributions across the continent.^{47,130} *F. tularensis* subsp. *holarctica* was found along the northwestern coast and along the tributaries of the Mississippi River. In contrast, the subspecies *tularensis* spanned the region from the east coast to Arkansas, Oklahoma, Texas, and Louisiana in the south; South Dakota in the north; and the Sierra Nevada in the west. Genetic analysis of the subspecies *tularensis* in this vast region revealed that type A1 is found primarily in the eastern United States, whereas most type A2 clusters to the West.^{83,87,130} This spatial separation of subspecies *tularensis* clades A1 and A2 coincides with the distribution of vectors *A. americanum* and *D. variabilis* in the East and *D. andersoni* and *Chrysops discalis* (deer fly) in the West. The spatial clustering of A1 and A2 also coincides with the distribution of an important host, cottontail rabbits, *Sylvilagus floridanus* and *Sylvilagus nuttallii*, respectively.⁴⁷

Whole-genome sequencing of A1 isolates has revealed three major subgroups whose names are consistent with phylogenetic nomenclature within *F. tularensis*. All strains of A1a belong to the A1.12 subgroup, with A1b distributed among A1.3, A1.8, and A1.12. Using this method, it appears that the geographic origin of the A1 group as a whole may be the central United States.¹¹

PATHOGENESIS

Bacterial and Host Interactions

Much of the knowledge regarding interactions between *F. tularensis* and the host was derived from experimental studies using live attenuated

strains. During World War II, live attenuated strains of *F. tularensis* were developed in the Soviet Union in an effort to produce a vaccine.^{114,142} In 1956, a mixture of attenuated strains of *F. tularensis* subsp. *holarctica* was transferred from the Soviet Union to the United States. From this mixture, a strain of suitable virulence was selected, tested for safety and efficacy, and designated *F. tularensis* live vaccine strain (LVS).^{38,40,72} This strain has been used extensively in experimental studies on the development of immunity in humans.

Capsulated *F. tularensis* organisms are thought to be opsonized by human macrophages and dendritic cells through the activation of complement, especially C3, and binding to the complement receptor 3 (CD11b/CD18).⁹ The interaction of complement-coated *Francisella* with the macrophage membrane initiates an actin-dependent process that engulfs the bacterium in an asymmetric, spacious pseudopod loop that forms the phagosome.^{25,27} The organism is able to survive and replicate within macrophages (i.e., *looping phagocytosis*).²⁵ The phagosomes are surrounded by a dense, fibrillar coating that begins to disintegrate approximately 3 to 4 hours after infection, a process that allows bacteria free access to the cytoplasm.²⁶ Approximately 24 hours after infection, replication of cytosolic *Francisella* induces apoptosis that leads to cell death and release of bacteria.

Tularemia is followed by effective immunospecific protection of the host; reinfection has been documented.¹⁵ Studies in which the infecting bacteria were suppressed by the use of a bacteriostatic agent such as tetracycline showed that protective immunity seems to be activated approximately 2 weeks after onset of the disease. When tetracycline treatment was initiated on the day of onset of tularemia and was given for 10 days, early relapses were common occurrences. When tetracycline treatment was administered for 14 days, relapses occurred less frequently, indicating that protective immunity had begun to arise.¹²¹

Innate immunity involving interferon- γ (IFN- γ), tumor necrosis factor- α (TNF- α), and interleukin-12 (IL-12) and the cells that produce these cytokines (i.e., natural killer cells, neutrophils, and macrophages) are thought to help control the initial phase of primary infection by curtailing the replication of *F. tularensis*.²⁸ Approximately 2 to 3 weeks after infection, *F. tularensis* elicits humoral and cell-mediated immune responses. Both responses reach maximal levels during the second week after infection.²⁴

Because *F. tularensis* is described as a facultative intracellular parasite, the general consensus is that long-term control and clearance ultimately depend on cell-mediated immunity, as they do in infections with *Listeria monocytogenes* and *Mycobacterium tuberculosis*.^{85,133,157} This finding was confirmed by several trials showing that vaccination with killed tularemia preparations, despite inducing agglutinating serum antibodies, provided poor protection.^{15,72,120} Numerous studies showed that passive transfer of mononuclear leukocytes from infected animals to noninfected animals conferred resistance when the nonimmunized animals were challenged with a virulent strain.¹²⁶ Ultimately, tularemia-specific CD4⁺ and CD8⁺ T lymphocytes are responsible for clearance of the bacteria.^{31,33,42,154}

Infection with LVS disrupts the production of proinflammatory cytokines from human macrophages and endothelial cells.^{50,138} This event is consistent with the lack of increase in proinflammatory cytokines, with the exception of a slight increase in IFN- γ during the early phase of the infection, in humans with ulceroglandular disease.

The importance of the humoral immune response in tularemia has recently been recognized.⁸⁵ Although the presence of immunoglobulin A (IgA) antibodies in nasal secretions correlates with resistance to infection by aerosolized organisms, earlier work by Bellanti and associates⁸ showed that humoral immunity plays an important role, especially in pulmonary tularemia. Specific antibodies probably are involved initially in delaying the infection, allowing time for the induction of cytokine production and specific T-cell-mediated immunity. This is consistent with the observation that although neutrophils have only a minor role in resistance to infection, mice depleted of CD4⁺ T cells or CD8⁺ T cells, or both, remained capable of controlling and partly resolving a primary sublethal *F. tularensis* infection.³¹ Antibodies may function as opsonins for macrophages and neutrophils, but the level of anti-tularemia antibody does not correlate with protection.¹³⁶ Elkins and associates⁴¹ showed that mice deficient in B cells do not succumb to sublethal doses of tularemia during a primary infection. However, in secondary infection,

the cytokines from B cells modulate the response of neutrophils against tularemia-infected hepatocytes and prevent the uncontrolled degranulation of neutrophils that may lead to severe tissue damage and poor clinical outcome.^{14,30,35}

The role of neutrophils in the control of *Francisella* infection is thought to be minor but necessary. McCaffrey and Allen¹⁰⁰ showed that neutrophils, like macrophages and dendritic cells, rapidly opsonize *Francisella* but are prevented from mounting the respiratory burst to kill the organism. The organisms then escape to the cytosol of the neutrophils and replicate. However, studies in which neutrophils were depleted from mice showed that mice given a sublethal dose of the LVS or mice chronically infected with LVS became susceptible to infection and died.¹²⁵ Although the mechanism of action of neutrophils in these cases is unclear, it may involve direct lysis of LVS-infected hepatocytes.³⁰

Persistence of immunity to *F. tularensis* depends on the T-cell response to a variety of antigens; the response may not be seen for as long as 2 weeks after exposure. Poquet and associates¹¹⁵ showed that virulent strains of *F. tularensis* produce high levels of phosphoantigens that cause a proliferation in γ/δ T cells to a greater extent than does exposure to the LVS. The reduced number of this T-cell subtype in vaccinated individuals could explain the lack of complete protection seen in vaccinated laboratory workers. As with membrane proteins stimulating an α/β T-cell response, heat shock protein chaperones such as DnaK and Cpn60 also create a nonimmunodominant proliferation of T cells in immunized individuals.⁴⁵ Denaturation of the protein or carbohydrate of a macromolecular antigen of *F. tularensis* showed that T-cell reactivity was associated with only protein determinants, whereas human immune serum reacts mostly with carbohydrate determinants of the organism.^{2,39}

Invasion and Disease Production

A single *F. tularensis* organism of a virulent strain can produce fatal infection in susceptible animals such as mice, guinea pigs, and hamsters.¹⁵⁸ As few as 10 organisms of a virulent strain injected intradermally or 25 organisms given by aerosol can produce systemic disease in human volunteers.⁷² The organism gains access to the human body through the skin, conjunctiva, oropharynx, respiratory tract, or gastrointestinal tract. It spreads by the lymphatics or hematogenously, and bacteremia usually develops during the first week of infection (3 to 12 days).⁸¹ Infection commonly involves the skin, regional lymph nodes, liver, spleen, and lungs. Rarely, the gastrointestinal tract and the central nervous system also are involved.

Histopathologic examination of mammals experimentally infected with *F. tularensis* indicates that the organism disseminates and causes cellular changes in a manner typical of intracellular parasites. After the organism is introduced into a susceptible host, multiplication occurs locally, with early spread to regional lymph nodes occurring within 48 to 96 hours.^{40,49} The developing cutaneous ulcer or soft tissue focus goes through a series of changes in which polymorphonuclear leukocytes are replaced by macrophages. In time, necrosis, epithelioid cell infiltrates, giant-cell formation, and true granulomas may develop.^{62,103,123} Organisms are difficult to demonstrate in tissue but occasionally are found at the periphery of lesions. In addition to the development of classic necrotic and granulomatous lesions, degeneration of the parenchyma in the liver and spleen may occur, as may marked hyperplasia of the reticuloendothelial system. Granulomas can organize to form microabscesses and abscesses.

The pace of the illness depends on the virulence of the strain, inoculum size, portal of entry, and immune status of the host.⁶⁶ When organisms enter the blood circulation, typical endotoxemia may ensue, sometimes in association with acute rhabdomyolysis.⁷⁹

Autopsies of fatal cases of tularemia in humans have confirmed the findings in experimental animals.^{60,94,111} Lymph nodes from patients with nonfatal disease have shown follicular hyperplasia with conglomerates of macrophages and caseating granulomas.^{85,94,96,130} These findings are similar to those seen in miliary tuberculosis. Tularemia and tuberculosis may be histopathologically distinguishable only because of the difference in timing of the development of tissue changes,⁸⁶ a difference related to the rapid replication of *F. tularensis*.

CLINICAL MANIFESTATIONS

Regardless of the portal of entry, the mode of onset of tularemia and the general features of the disease are the same. The usual incubation period of tularemia is 3 to 4 days, with a range of 1 to 21 days. The onset of symptoms is abrupt. Symptoms include fever, with a temperature usually higher than 39.4°C (103°F), chills, headache, myalgia, anorexia, vomiting, and occasionally photophobia. Fever may be continuous or biphasic, with an intermittent period of defervescence. In untreated patients, fever may persist for longer than 3 weeks. Physical findings usually include lymphadenopathy, hepatosplenomegaly, pharyngitis, and skin lesions. Temperature-pulse dissociation has been described in as many as 42% of cases.^{46,57} A variety of skin rashes (e.g., maculopapular, vesicular, and pustular rashes; erythema nodosum,¹¹² erythema multiforme¹²⁴) may appear during the second week of illness and can last for a few days to several weeks.^{6,81,134}

Laboratory studies, including a complete blood cell count, erythrocyte sedimentation rate, and urinalysis, usually are not helpful in diagnosing tularemia. Sterile pyuria has been reported in 22% to 32% of patients with tularemia.^{46,110} Sterile pyuria combined with a history of fever, dysuria, or low back pain led to an erroneous diagnosis of urinary tract infection in 11% of the patients reported by Evans and associates.⁴⁶ Increased liver function test values with jaundice and atypical lymphocytosis also have been described.^{58,61} The six clinical syndromes of tularemia can be classified by the portal of entry: ulceroglandular, glandular, oculoglandular, typhoidal, oropharyngeal, and pneumonic.

Ulceroglandular and Glandular Tularemia

Ulceroglandular and glandular tularemia are the most common forms of the disease in children and adults.^{21,20,71,97,153} In ulceroglandular disease, the organism gains access through the skin, and approximately 2 days after the onset of general symptoms, the patient reports tender, swollen lymph nodes, most commonly in the axillary or inguinal areas.

Within 24 hours, the portal of entry may become evident when a painful, swollen papule develops distal to the regional node. This papule ruptures and leaves a punched-out ulcer with raised edges. The ulcer is indolent and, in untreated cases, may persist for longer than a month. The skin over the involved nodes may be inflamed. In untreated cases, approximately 50% of the lymph nodes suppurate and drain. In other cases, the nodes remain firm, enlarged, and tender for several months. Mild, generalized lymphadenopathy and enlargement of the liver and spleen may occur.

Glandular tularemia is almost identical to the ulceroglandular form, except that the portal of entry cannot be identified. The consensus is that the portal is an insignificant break in the skin. Isolated cases of cervical lymphadenopathy have been related causally to *F. tularensis* infection.

Oropharyngeal Tularemia

The infection is introduced into the oropharyngeal mucosa through infected, inadequately cooked meat or contaminated water.^{82,90,140} The organisms may enter the body through abrasions or aerosolization during chewing or swallowing. Local involvement consists of acute tonsillitis with cervical adenitis.^{13,82} The tonsils may be covered by an exudate or membrane that extends in all directions and may resemble a diphtheritic membrane. Complaints of sore throat usually are out of proportion to the visible pathologic features, but ulcers sometimes form.

The cervical lymph nodes may suppurate. Infrequently, *F. tularensis* invades the lower portions of the gastrointestinal tract, in which case vomiting, diarrhea, and abdominal pain are prominent symptoms. Awareness of the ability of *F. tularensis* to cause oropharyngeal involvement is important for physicians caring for children.^{70,82,92,140}

Oculoglandular Tularemia

In oculoglandular tularemia, which accounts for approximately 1% of all cases, the portal of entry is the conjunctival sac, which may become inoculated by rubbing with contaminated fingers, having contact with infected water, splashing of infected liquids, or inhaling infected aerosols. The eyelids may become edematous, and the conjunctivae may be inflamed and painful. Numerous, small, sharply defined, yellowish

nodules and ulcers may develop on the palpebral conjunctivae.¹²⁹ In some cases, corneal ulceration occurs.

As seen in cat-scratch disease, the Parinaud complex of unilateral preauricular lymph node involvement and conjunctivitis can result.^{129,131} The regional lymph nodes, the preauricular nodes, and the submaxillary and cervical nodes are swollen, tender, and painful.¹¹² In severe cases, the axillary nodes may be involved.⁵³

Typhoidal Tularemia

Typhoidal tularemia may manifest as a fever of unknown origin. The symptoms are those of acute septicemia, with no localized skin lesions and often without lymphadenopathy. Patients are seriously ill, and shock may develop. The symptoms and signs of typhoidal tularemia are toxemia, continuous fever, myalgia, and severe headache. Patients may be delirious and may exhibit meningismus. Patients often complain of having severe pharyngeal pain, but pharyngeal lesions may not be evident. Diarrhea occurs in this form of tularemia in adults and children. Patients sometimes have a dry cough and retrosternal pain. Pleuropulmonary involvement is a common finding in adults with typhoidal tularemia.³⁷

In children, typhoidal tularemia can be the result of ingestion of the causative agent, and necrotic lesions may occur throughout the bowel.³⁷ Inhalation of aerosolized organisms is a more common mode of acquisition in adults (e.g., laboratory workers, farmers).

Pneumonic Tularemia

The pneumonic form of the disease occurs most commonly in laboratory workers and is the most severe form of the tularemia. Pneumonic tularemia may be acquired by the aerogenic route,^{36,48,139} or it may be associated with other forms of tularemia, particularly the typhoidal type. Dienst³⁷ and Miller and Bates¹⁰⁵ published outstanding descriptions of pleuropulmonary tularemia. Miller and Bates stressed that the symptoms and signs of pleuropulmonary tularemia are nonspecific and vary with the location and degree of pulmonary involvement.

The various radiographic features may be confused with those of tuberculosis, mycotic infection, common bacterial pneumonia, lymphoma, or carcinoma of the lung. In the series of 29 patients by Miller and Bates,¹⁰⁵ pleural effusion developed in 6 patients. Pleural effusions can contain more than 3 g of protein/100 mL and more than 1000 white blood cells/mm³ with a lymphocytic predominance.⁵⁹ Because of the necrotizing nature of the pathologic process, the lung may heal with residual fibrosis or calcification. In other instances, the disease is so fulminant that death occurs before the pathologic features can progress fully.

Additional Clinical Manifestations

Subcutaneous nodules resembling those seen in sporotrichosis can be found on physical examination. The nodules usually are distributed on the anterior or posterior surface of the arm and may extend from the primary lesion to the regional lymph nodes. Initially, these nodules are firm and movable, but they later become fixed to the skin and may suppurate. They vary in size from less than a centimeter to more than several centimeters if they become confluent. Other unusual manifestations of tularemia include pericarditis, appendicitis, peritonitis, liver abscess, cerebellitis with ataxia, meningitis, encephalitis, osteomyelitis, rhabdomyolysis, and venous thrombosis.^{32,65,117}

The incidence of these forms among children is somewhat different from that for adults. Although the pneumonic form previously was thought to be rare in children,⁹² it has been shown that the occurrence of pneumonic tularemia is not uncommon. In a 1985 study by Jacobs and associates,⁷¹ 14% of pediatric tularemia cases were the pneumonic form. This percentage contrasts with the absence of pulmonary involvement in a series of 48 children with tularemia reported by Levy and associates⁹² in 1950.

The distribution of these forms of tularemia also varies with the geographic location. In a report of 67 children with tularemia in Finland, 79% of cases were of the ulceroglandular form and 8% were glandular.¹⁴³ This distribution is significantly different from that in the United States. In the study by Jacobs and associates,⁷¹ who reported 28 cases of tularemia among children, 45% were ulceroglandular, and 25% were glandular. Later from the same region, of the 30 cases described, 57% were

ulceroglandular disease.¹²⁸ The authors of the Finnish study attributed the higher proportion of the ulceroglandular form in their study to heightened awareness of the disease and early diagnosis. The differences also could be explained by the different strains of *F. tularensis* and different vectors in the two regions.

F. tularensis also can occur in the setting of an immunocompromised host. The pneumonic form of tularemia was reported in a patient with chronic granulomatous disease requiring lobectomy.⁹⁸ Pneumonic tularemia also was seen in a patient who previously had undergone peripheral blood stem cell transplantation for acute myelogenous leukemia (it resulted in a solitary pulmonary nodule), in a patient infected with human immunodeficiency virus (HIV),^{61,106} in a kidney transplant recipient,⁸⁴ and in a patient with graft-versus-host disease.¹⁵¹ Pneumonic tularemia was identified in a patient with a ventriculoperitoneal shunt.¹¹³ Impairment of normal immunity can prevent adequate protection from *F. tularensis* and necessitate more prolonged therapy.

DIAGNOSIS

The diagnosis of tularemia is established by a thorough history of possible exposure, clinical manifestations, and serial serologic tests. Obtaining a careful family history often is rewarding because several family members commonly are infected simultaneously. In some instances, however, a positive history never is elicited.

Tularemia has no absolute pathognomonic features. In diagnosing tularemia, the physician must account for the endemic rate of the disease in the area, season of the year, clinical manifestations of the disease, precise epidemiologic setting,¹³² and unresponsiveness of the disease to antibiotics that are not effective against tularemia.

The diagnosis is confirmed by the standard agglutination test, which is available commercially and is reliable. Unfortunately, it may not provide an early diagnosis because agglutinating antibodies may not be detectable until the second week of illness. Occasionally, seroconversion is not confirmed until the patient has experienced 4 to 6 weeks of illness. In rare cases, agglutinating antibody may never be detected.

A fourfold increase in convalescent titer confirms the diagnosis (with an initial minimum titer of 1:160), but a presumptive diagnosis should be considered in patients with acute titers of 1:160 or greater. This titer may indicate current or past infection, but in a clinically suspicious case, it should be considered an indication for presumptive therapy. Titers of 1:1280 or greater often develop in patients with active disease as the initial manifestation of seroconversion. The agglutination test is specific, but cross-reaction with *Brucella* spp., *Legionella* spp., or other gram-negative bacteria can occur. Antibiotic therapy does not prevent the development of agglutinating antibodies. A single titer of 1:128 or greater determined by microagglutination or with a fourfold increase with convalescent testing is also considered positive. Commercially developed enzyme-linked immunosorbent assay (ELISAs) have also been found to be a useful tool.²³

Polymerase chain reaction (PCR)-based assays are used for early detection of *F. tularensis* infection.^{12,78,95} The PCR test is effective in establishing the diagnosis of tularemia even when samples of a tularemic ulcer are obtained 1 to 14 days after infection.¹²⁷ When PCR and culture of the wound and blood were compared with agglutination tests, the sensitivity of PCR was 75%, and the sensitivity of culture was 62%.⁷⁵ In addition to increasing the safety for laboratory personnel, the PCR method was more sensitive and detected infection at earlier stages. In contrast to conventional PCR-based assays, real-time PCR (rt-PCR) is more specific and 10 times more sensitive.¹⁴⁶ These assays are not widely commercially available.

In a Norwegian field study, a rapid immunochromatography assay proved inexpensive, time efficient, and portable in contrast to PCR and ELISA, but this method was less sensitive than PCR.¹⁰ This assay could accelerate identification and treatment decisions in clinical practice.

Gram-stained smears of patient specimens such as exudate and sputum usually do not reveal the organism. However, collecting the specimens poses no danger, and examination of direct smears helps rule out other causative agents. Specimens should not be cultured for *F. tularensis* in the usual hospital or diagnostic laboratory because isolation of the organisms in facilities other than a level P3 laboratory is

hazardous to laboratory personnel. If confirmation by culture is indicated, physicians should notify the laboratory of the potential for the specimen to contain *F. tularensis*, so that appropriate laboratory precautions can be taken.

The differential diagnosis of tularemia depends on the clinical form of the disease. Ulceroglandular and glandular tularemia must be differentiated from disease caused by ordinary bacterial pathogens such as *Streptococcus* and *Staphylococcus*, from disease caused by *M. tuberculosis* and atypical mycobacteria such as *Mycobacterium marinum*, and from anthrax, HIV infection, and cat-scratch disease. In older patients with inguinal lymphadenopathy, lymphogranuloma venereum, granuloma inguinale, and other sexually transmitted infections should be considered. Occasionally, sporotrichosis and infectious mononucleosis are diagnosed in these patients.

Oculoglandular fever is somewhat more distinctive, but the possibility of disease caused by common bacterial pathogens such as *L. monocytogenes* infection, herpes zoster, inclusion conjunctivitis, and keratoconjunctivitis must not be ruled out. Oropharyngeal tularemia must be differentiated from streptococcal tonsillopharyngitis and corynebacterial disease. Typhoidal tularemia can be confused with ordinary bacteremia and must be differentiated from the more common bacterial and enteric disease and from malaria, miliary tuberculosis, brucellosis, and typhoid fever. Tularemic pneumonia must be differentiated from other bacterial and nonbacterial pneumonia, including tuberculosis, *Mycoplasma* infection, legionnaires' disease, psittacosis, viral pneumonia, Q fever, fungal infection, and chemical pneumonitis.

TREATMENT

Gentamicin is recommended for the treatment of tularemia.¹⁵³ The dosage for children is 5 mg/kg daily in two divided doses administered intravenously or intramuscularly. The duration of therapy is usually 7 to 10 days, with more severe disease requiring a longer duration of treatment. In mild to moderate cases in which patients become afebrile within 48 hours of starting antimicrobial therapy, a 5- to 7-day course can be used. Defervescence and alleviation of other signs and symptoms usually occur within several days. Response may be delayed if the lymph nodes have progressed to suppuration requiring drainage.

If available, streptomycin given intramuscularly can be used. The recommended dose of streptomycin is 30 to 40 mg/kg per day administered intramuscularly in two divided doses for 7 days. If a patient has mild symptoms initially or responds dramatically to therapy, an alternative streptomycin regimen of 30 to 40 mg/kg per day for 3 days followed by 15 to 20 mg/kg per day for 4 days may be given intramuscularly. In severe cases or if a child does not become afebrile and asymptomatic within a few days of starting therapy, extension of treatment beyond 7 days is indicated. Streptomycin-resistant strains of tularemia are reported, but they are rare. Other aminoglycosides (e.g., tobramycin) are ineffective in treating tularemia and should not be used.

Bacteriostatic agents such as tetracycline (or doxycycline) and chloramphenicol have been used to treat tularemia, with cure rates of 88% and 77%, respectively. However, these agents are considered suboptimal for the treatment of tularemia because of a high incidence of relapse after therapy is stopped.⁴³

Although in vitro susceptibility testing indicates that the third-generation cephalosporins may be effective against *F. tularensis*, one report showed treatment failure in eight children given ceftriaxone.³⁴ Treatment with other antibiotics has been reported sporadically in the literature.^{63,91} Fluoroquinolones have been used with success when treating infections caused by the subspecies *holartica*.^{4,104,106,122,135} An efficacy trial in Sweden of ciprofloxacin demonstrated successful outpatient management of *F. tularensis* in 10 of 12 patients 1 to 10 years of age.⁷⁶ The dosage used was 15 to 20 mg/kg per day given in two divided doses for a 10- to 14-day course of therapy. Defervescence occurred on the fourth day of treatment. The lack of successful treatment data for the subspecies *tularensis* and the issues related to the use of fluoroquinolones in children younger than 18 years of age limit the use of these medications in North American children.¹⁵³

Hearing screening should be considered before initiation of streptomycin or gentamicin therapy. If the child has preexisting hearing loss,

the alternative streptomycin regimen or gentamicin therapy can be considered, with close monitoring of serum levels in severe cases. In these cases, audiologic evaluation is indicated after therapy is initiated.

Bed rest and supportive therapy are indicated. In a severely ill patient who shows signs of endotoxic shock, appropriate monitoring and admission to an intensive care unit are indicated, and corticosteroid therapy should be considered. Suppurative lymph nodes may require surgical drainage even after an appropriate course of therapy. In most cases, this does not represent a treatment failure and does not require additional antimicrobial therapy. Complicated cases (e.g., meningitis) may require treatment with more than one antimicrobial agent.

Before the advent of effective antimicrobial therapy, tularemia often was a protracted illness that lasted weeks or months. Subsequently, a long period of convalescence was necessitated by debility. Antibiotics have interrupted the natural history of the disease. When the disease is diagnosed promptly, the course usually is less than a month. As a result of administering appropriate antibiotic therapy, the mortality rate has declined from 5% to 30% to less than 1%, except in cases of fulminant pneumonic and typhoidal disease.

PREVENTION

Prevention of human tularemia depends on prevention of exposure to the vectors or contaminated animal tissue. Children living in areas of tick endemicity should have their skin and hair checked frequently for ticks. Ticks should be removed carefully with tweezers (not with fingernails) by pulling perpendicular to the skin where the ticks have attached. Care should be taken not to squeeze the ticks between the fingers. Persons living in tick-infested areas should wear clothing with tightly fitting cuffs at the wrists and ankles when staying outdoors. Tick repellents should be used with caution on children. Prophylaxis with antimicrobial agents has not proved effective in preventing disease in children with tick bites.

Children should be warned against handling sick or dead rodents or rabbits. Incineration or burial should be used to dispose of rabbits caught by household pets. Rubber gloves should be worn for preparing game animals, and the meat should be cooked thoroughly before eating. Hunters, especially rabbit hunters, should take precautions against contracting tularemia.

A wide range of approaches to vaccine development is being evaluated, but no vaccine against tularemia has been licensed.²⁹

Relatively few species of the genus *Haemophilus* are pathogenic to humans, and most that cause human disease are encapsulated or unencapsulated strains of *Haemophilus influenzae*. The latter bacteria are small, gram-negative pleomorphic coccobacilli that are considered to be normal constituents of the microbial flora of the upper respiratory tract of humans.^{237,268} Strains without polysaccharide capsules often cause infections of mucosal surfaces, such as otitis media, bronchitis, conjunctivitis, sinusitis, and types of pneumonia.^{289,295} Encapsulated strains, especially *H. influenzae* type b (Hib), cause invasive diseases such as septicemia, meningitis, septic arthritis, cellulitis, epiglottitis, pneumonia, and empyema. Before Hib vaccines became widely available, *H. influenzae* was the leading cause of bacterial meningitis in the United States and most other countries, and it was an important cause of other bacteremic illnesses, primarily in young children.^{50,258,473}

The organism now known as *Haemophilus influenzae* first was described in 1892 by Robert Pfeiffer, who isolated it from the lungs and sputum of patients during the 1889 to 1892 pandemic of influenza. He proposed that the organism was the cause of influenza, and it initially was known as the Pfeiffer influenza bacillus.³³³

The bacteria were difficult to culture on routine media until investigators appreciated that supplementation with X (i.e., hemin) and V (i.e., nicotinamide adenine dinucleotide [NAD]) factors was required for its growth. By the turn of the century, the organism had been recovered from the blood and cerebrospinal fluid (CSF) of young children with meningitis. Although doubts remained about the etiologic role of the Pfeiffer bacillus as the cause of influenza, not until the influenza pandemic of 1918 was its etiologic role questioned seriously.

In 1920, the organism was renamed *Haemophilus influenzae* to acknowledge its inappropriate historic association with influenza and to emphasize its requirement of blood factors for growth (from the Greek *haemophilus*, or “blood loving”).⁴⁷⁵ In 1933, the viral cause of influenza was discovered, which refuted any remaining confusion about the erroneous association between *H. influenzae* and influenza virus.

Key concepts relevant to the development of treatment and prevention modalities were derived from the pioneering work of Margaret Pittman in the early 1930s.^{339,338} Paralleling earlier research on the pneumococcus, she defined two major categories of *H. influenzae*: encapsulated and unencapsulated strains. Among the encapsulated strains, she characterized six distinct serotypes (i.e., designated a through f), which now are known to differ biochemically in the composition of their polysaccharide capsules (Table 133.1). She observed that *Haemophilus influenzae* type b (Hib) strains were recovered primarily from the blood and CSF of young patients with meningitis and that unencapsulated strains and other *H. influenzae* serotypes were recovered primarily from respiratory tract secretions.

Pittman demonstrated that antibody to Hib capsule conferred type-specific protection against lethal infection in rabbits. This observation led to the use of antiserum prepared by immunization with formalin-killed Hib, initially in horses and later in rabbits, as the first treatment of disease. Before this development, Hib meningitis and other forms of invasive Hib disease were almost always fatal.⁴⁵¹ However, not until the late 1930s did treatment of children with meningitis with Hib antiserum and sulfonamides substantially reduce the case-fatality rate.⁶⁷

In 1933, Fothergill and Wright¹³⁰ described the age-related risk of acquiring *H. influenzae* meningitis, which affected mostly children younger than 5 years of age. They noticed the correlation between the age-related risk of disease and the absence of bactericidal antibodies. Later researchers identified antibody to Hib capsule as the major antibody contributing to the protective activity of bactericidal serum.^{202,380} These observations suggested that naturally acquired type b anticapsular

antibody is protective and that early stimulation of protective immunity with vaccines might be possible.

Unfortunately, the advent of effective antimicrobial agents focused attention away from the need for primary prevention. Even with effective antimicrobial therapies and excellent hospital care, significant mortality (approximately 5%) and neurologic morbidity (approximately 20%) remained.^{98,99} Ultimately, appreciation that the morbidity and mortality of the disease could never be eliminated completely by treatment gave impetus to the development of vaccines for prevention.

In the early 1970s, investigators purified and characterized the type b capsular polysaccharide (i.e., polyribosylribitol phosphate [PRP]) and proposed it as a vaccine candidate. Subsequently, the protective efficacy of a PRP vaccine against invasive Hib disease was demonstrated in older children in a 1974 field trial conducted in Finland.³²⁶ This and other studies culminated in the licensure of PRP vaccine in the United States in 1985, rendering it the first vaccine available for the prevention of Hib disease.⁶² Unfortunately, this vaccine induced variable immune responses and incomplete protection in older children and provided no protection for young infants, those who had the greatest risk of acquiring Hib disease.⁴⁶¹ Improved vaccines used polysaccharide-protein conjugate techniques, and four such vaccines were licensed for use in children. Three of these vaccines were shown to protect young infants against Hib disease,^{37,370,444} and with the universal immunization of young infants, invasive Hib disease has been almost eliminated in many populations.^{80,143,193} Unfortunately, Hib disease continues to be a significant cause of morbidity and mortality among children in resource-poor countries around the world where access to Hib vaccines is still limited.^{282,464,484}

Haemophilus influenzae

MICROBIOLOGY

Morphologic and Cultural Characteristics

H. influenzae is a small, gram-negative coccobacillus that in clinical specimens can appear filamentous or pleomorphic, especially when obtained from patients who previously have received antibiotics. The nonmotile, non-spore forming, and facultatively anaerobic organism requires two supplemental factors for in vitro growth.²³⁷ The X factor (i.e., hemin) is a heat-stable, iron-containing protoporphyrin essential for activity of the electron transport chain, which is important for aerobic growth. The heat-labile V factor is the coenzyme NAD. Both factors occur in erythrocytes and are released by appropriate heating or enzyme lysis of the red blood cells, which permits growth on chocolate agar. The requirement for these factors for growth remains the primary basis for the laboratory differentiation of *H. influenzae* from other *Haemophilus* species.^{20,237}

The growth of *H. influenzae* is fastidious, and clinical specimens need to be inoculated promptly onto appropriate media, such as chocolate agar.²³⁷ The organism can be grown in most enriched liquid or solid media supplemented with X and V factors. Although not mandatory for growth, 5% to 10% carbon dioxide makes some strains grow better. In blood or liquid media, *H. influenzae* may not grow to sufficient quantity to result in visual turbidity, and to detect positive cultures, blood and CSF cultures should be assayed for release of carbon dioxide or routinely subcultured at 24 to 48 hours.

After overnight incubation on solid media, colonies appear that are 0.5 to 1.5 mm in diameter and usually rough or granular in appearance. Encapsulated strains typically produce slightly larger colonies that are mucoid or glistening. Fermentation reactions and other metabolic activities vary and therefore are not particularly useful for identification. However, a biotyping scheme based on the metabolism of indole, urea, and ornithine decarboxylase activity has been used to subtype strains.²³⁷

Capsular Polysaccharides

Several surface structures of *H. influenzae* contribute to the organism's pathogenicity, but one of the most important is the capsular polysaccharide. Strains can express one of six unique polysaccharide capsules (i.e., a, b, c, d, e, or f) (see Table 133.1) or lack capsule expression completely (i.e., nontypeable strains). The Hib capsule is of particular clinical, pathogenic, and immunologic importance because Hib accounts for 95% of all strains that cause invasive disease in nonimmunized populations.^{50,258,265} The Hib polysaccharide consists of a repeating polymer of ribosyl and ribitol phosphate (PRP) that has a 1-1 linkage.¹⁰²

The genes involved in production of the Hib capsule have been cloned and consist of two repeating 17-kb DNA fragments separated by a 1-kb bridge region (i.e., *bexA*)^{188,222}; 98% of Hib organisms tested contain this duplication.²²² Encapsulation often is unstable, with loss of capsule production associated with loss of one 17-kb repeat.²²¹ These strains produce the type b capsule, but in barely detectable amounts. Release of the Hib capsular antigen in the body fluids of infected individuals can be detected by specific immunologic techniques (i.e., latex agglutination) that are useful for rapid diagnosis.^{207,463} The other capsular serotypes are composed of hexose rather than pentose sugars,^{102,103,435,436} and these strains occasionally result in invasive disease.^{53,95,228,439}

Noncapsular Cell Wall Antigens: Proteins

The cell envelope of *H. influenzae* is typical of other gram-negative bacteria, consisting of a cytoplasmic membrane, a peptidoglycan layer, and an outer membrane that represents the outermost layer of the envelope. The outer membrane contains an array of proteins, lipopolysaccharides (LPSs), and phospholipids, many of which serve important functional roles for the organisms. Over the past 2 decades, significant advances have been made in our understanding of these many outer membrane components and their contributions to the pathogenesis of disease.^{289,295}

Early laboratory investigations of *H. influenzae* identified and characterized a number of major and minor outer membrane proteins of the organism.^{32,287,288,294,310,396} However, an understanding of the functional roles of most of these proteins was lacking. Subsequent studies have

helped to clarify the roles in disease pathogenesis of an increasing number of these proteins. Several proteins are important for attachment of *H. influenzae* to host respiratory mucosal tissues.^{55,59,84,195,285,429} Other surface proteins play a central role in bacterial acquisition of iron, a phenotypic trait critical for survival of the organism in the human host.^{5,199,215,267,283,480} Studies have identified bacterial surface proteins important in resistance of *H. influenzae* to components of the host innate immune system, the first line of defense in the nonimmune host.^{96,174,175,177,266,415} The availability of the completed genomes of several representative *H. influenzae* strains has also helped to increase the rate of discovery of other proteins important in disease pathogenesis.^{91,110,152,304,447}

Noncapsular Cell Wall Antigens: Lipooligosaccharide

Early studies of *H. influenzae* lipooligosaccharide (LOS) demonstrated that although it differed chemically and structurally from the LPS of *Enterobacteriaceae*, it shared several biologic properties with the latter molecule. LOS purified from Hib produced a dermal Schwartzman reaction, was lethal to mice, caused a febrile response in rabbits, evoked polyclonal B-cell activation, and had limulus lysate activity.¹²⁸ Human leukocytes incubated with *H. influenzae* LOS generated potent procoagulant activity,²⁸⁰ a property that may be relevant to understanding the mechanisms responsible for intravascular coagulation in severe infection.

Over the past 20 years, knowledge concerning the genetics, structure, biosynthesis, and role in pathogenesis of the *H. influenzae* LOS has increased greatly. The structure of *H. influenzae* LOS consists of a conserved triheptose inner core linked by a single 2-keto-3-deoxy-octulosonic acid molecule to lipid A, from which there are oligosaccharide extensions (i.e., outer core), mainly hexose sugars that vary from one strain to another.^{172,262,263,420} *H. influenzae* LOS lacks the repetitive side chains typical of gram-negative enteric bacteria but displays great complexity in its outer core sugars and other substituents such as phosphorylcholine^{465,466} and sialic acid.^{9,46} Several of these sugars and nonsugar substituents of *H. influenzae* LOS are phase variable.^{170,171,466} Phase variation is mediated by translational switching of genes that contain tetranucleotide repeats within the 5' ends of the respective reading frames.^{172,194,466} Phase-variable expression of several LPS components contributes to the pathogenesis of disease (discussed later).

IgA Proteases

IgA proteases are bacterial enzymes whose only known substrate is human IgA1. These secreted enzymes cleave the IgA heavy chain at specific sites.²¹⁸ IgA proteases are regarded as potentially important virulence factors because mucosal defense is in part IgA mediated. *H. influenzae* produces at least two distinct types of IgA protease that cleave different peptide bonds within the IgA1 hinge region.^{286,340} *H. influenzae* isolated from patients with disease express higher levels of IgA protease than strains isolated from asymptomatic carriers,⁴⁴⁹ suggesting that IgA protease is an important virulence factor for *H. influenzae*. Investigators have identified and characterized another IgA protease gene that occurs in about 40% of *H. influenzae* strains.^{120,296} This gene, designated *igaB*, is distinct from the previously characterized IgA protease gene, and it is associated with higher levels of IgA protease expression and with a greater likelihood of causing disease,¹²⁰ particularly in patients with chronic obstructive pulmonary disease.²⁹⁷ Products of both genes appear to be expressed simultaneously in the course of human infection caused by *H. influenzae*.²⁹⁶

Population Structure

Powerful typing techniques have been developed for identifying individual *H. influenzae* strains and defining the relationships between strains.^{276,306,332} These techniques have provided valuable information for a variety of epidemiologic studies and have defined the population structure for *H. influenzae* organisms as a whole.^{210,382}

Encapsulated *H. influenzae* can be grouped into two distinct primary phylogenetic divisions.³⁰⁶ The population structure of encapsulated *H. influenzae* is clonal. Most the invasive disease worldwide is caused by serotype b strains from a limited number of clones.²²² Strains producing serotype c, e, and f capsules belong to single divisions and have no close genetic relationships to strains of other serotypes.³⁰⁶

Serotype a and b strains occur in both primary phylogenetic divisions, probably as a result of transfer and recombination of serotype-specific sequences of the cap region between clonal lineages.^{223,306} In contrast to the encapsulated strains, the unencapsulated or nontypeable *H. influenzae* strains demonstrate substantial genetic diversity.^{91,107,210,305,332,382} Contributing to the genetic diversity of the nontypeable *H. influenzae* are apparently high rates of recombination between individual bacterial strains.^{77,82,142,276,421}

Antibiotic Resistance

Another important feature of *H. influenzae* is development of antibiotic resistance. Resistance to a wide variety of antibiotics (e.g., sulfonamides, trimethoprim-sulfamethoxazole, erythromycin, tetracycline, penicillin) has been described, but these antibiotics are not essential for therapy. Of greater importance is resistance to ampicillin, which was first identified in the mid-1970s,²⁶⁵ because it was the primary antibiotic used for the treatment of disease. Since then, ampicillin resistance has become widespread, and between 5% and 40% of all isolates in various parts of the world are now resistant.^{29,86,185,398}

The mechanism of resistance usually involves the production of plasmid-mediated β -lactamase enzyme, and resistant strains often are characterized by their plasmid or β -lactamase enzyme content.²⁰⁴ Non- β -lactamase-mediated ampicillin and ampicillin-clavulanic acid resistance have been reported among an increasing percentage of isolates from around the world, particularly for nontypeable *H. influenzae*.^{23,86,150,205,322} The resistance in these strains appears to be mediated primarily by alterations in specific penicillin-binding proteins.²⁹ Resistance to chloramphenicol usually is mediated by the enzyme chloramphenicol acetyltransferase.^{360,453} Although chloramphenicol-resistant strains are rare in the United States, they are more prevalent in some areas of the world, and strains resistant to both ampicillin and chloramphenicol have been reported.^{61,320,438}

Third-generation cephalosporins currently are the mainstays of therapy for invasive disease. Concern about the potential for increasing resistance to these highly effective agents further emphasizes the need for means to prevent disease.⁴³⁴

PATHOGENESIS

Acquisition and Carriage of Organisms

Illness caused by *H. influenzae* infection results from a series of pathogenic events beginning with exposure to the organism and followed by colonization of respiratory mucosal membranes.¹³¹ Under natural conditions, *H. influenzae* is exclusively a pathogen of humans, and it usually is transmitted asymptotically from person to person by transfer of respiratory secretions.^{185,318,324} The incubation period is unknown because many transmission cycles may occur before a susceptible person becomes ill. In some individuals, the organism can be carried in the upper respiratory tract for many months before it causes disease.^{87,350,401}

Typeable and nontypeable organisms may be part of the normal flora of the upper respiratory tract.¹⁹⁸ As many as 80% of individuals are colonized at some point with nontypeable strains.^{185,324,337,347} In the prevaccine era, Hib carriage rates were lowest among adults and young infants and highest among preschool-age children.⁴³⁷ In a prevaccine era study conducted at a childcare center in Dallas where no invasive infections occurred, the average rate of colonization with Hib was 10%.²⁹⁸ During the 18 months of the study, 71% of the children 18 to 35 months of age and 48% of the children 36 to 71 months of age were colonized at some time. Carriage rates were substantially higher in households or childcare centers in which a case occurred. For example, colonization prevalence rates among children in childcare centers where a case of invasive disease had occurred were as high as 58% to 91%.^{161,460} Within families in which a case of invasive disease occurred, rates of colonization of 60% to 70% among siblings and 20% among parents were observed.^{56,460} Whether the high carriage rates in these exposed semiclosed populations were the cause or the result of disease was not clear.^{268,279} Close contact among exposed susceptible individuals, as occurs within families and childcare centers, facilitated the risk of transmission and acquisition of disease.

Despite a low point prevalence of Hib pharyngeal carriage (1–5%) in the prevaccine era, most young children became colonized with Hib during the first 2 to 5 years of life,^{268,437} and specific Hib immunity developed in these colonized children.^{168,380} Hib strains were demonstrated to persist in the nasopharynx for months^{279,298} and often were not eliminated by treatment with antimicrobial agents that did not penetrate into respiratory secretions.^{390,391}

The relationship between carriage of Hib and the subsequent development of disease and immunity is not well understood. Factors that influence the efficiency of transmission and the ability of the organism to establish colonization also are poorly understood. Two factors that probably potentiate the risk for acquiring infection and invasive disease are the size of the bacterial inoculum⁴¹¹ and the presence of a concomitant viral infection.²²⁰

Data derived from animal models of infection may elucidate the dynamic nature of the colonization process. Inoculation of Hib organisms into the nose of infant animals results in local infection.^{284,363} In this model system, rhinorrhea was not observed, but nasopharyngeal washings revealed numerous polymorphonuclear leukocytes and organisms that reached maximal density in approximately 24 hours. Shortly thereafter, bacteremia could be detected in the animals.

With colonization of humans, Hib is found on the surface of the respiratory mucosa. Rarely, an organism can be observed by electron microscopy penetrating through a nasal mucosal epithelial cell.⁴¹¹ An acute inflammatory response to the submucosal bacteria occurs, but it is not marked. The exact mode of entrance of the organisms into the vascular compartment is unknown, but it is assumed that they enter through the lymphatics, probably carried by phagocytic cells, which are found in the submucosa. In support of this hypothesis, Rubin and Moxon³⁶³ detected early transient bacteremia in rats after nasal inoculation.

Pathogenesis of Mucosal Infections

Mucosal colonization and mucosal infections occur much more frequently than do invasive bacteremic infections, particularly in populations in which Hib vaccine is in widespread use. Mucosal infections, most of which are caused by nontypeable *H. influenzae*, still cause considerable morbidity and are associated with substantial health care costs.^{371,413,424}

Mucosal infections usually involve direct movement of organisms through the nasal ostia to the sinuses and up the eustachian tubes, where they cause otitis media, and down the bronchi, where they cause bronchitis and pneumonia. Bacteremia rarely is involved, and the infections typically are not life-threatening. These infections appear to be enhanced by antecedent viral infection,^{68,323} Eustachian tube malfunction,⁴¹⁸ foreign bodies, or mucosal damage from smoking or other irritants.³⁶⁷

Much research has focused on better understanding the molecular pathogenesis of mucosal surface infections caused by nontypeable *H. influenzae*. The same principles apply to the early steps in mucosal colonization by encapsulated *H. influenzae*. A model has been proposed to explain early events in the process.¹⁸³ After transmission from an *H. influenzae* carrier to a new host,⁸⁷ bacteria come in contact with the upper respiratory tract, where they must overcome the nonspecific mucociliary defenses if colonization is to persist.³⁸⁶ *H. influenzae* major outer membrane proteins P2 and P5 and probably other factors promote bacterial binding to mucus and help establish an early foothold for the bacteria in the upper respiratory tract.^{351,411} Local elaboration of LPS and other bacterial products then causes damage to ciliated cells and further impairs mucociliary function.⁴⁵⁶ Adhesins, including HMW1, HMW2, Hia, Hap, pili, protein E, and others, help mediate direct adherence to nonciliated epithelial cells.^{25,33,124,146,147,399,412}

Cleavage of IgA,^{120,296,297} invasion into cells and the subepithelial space,^{129,411,419} and phase and antigenic variation of surface antigens facilitate evasion of local immune mechanisms.^{21,22,70,90} Binding and uptake of iron and heme allow organisms to persist on the respiratory mucosa despite the relative scarcity of these nutrients.^{267,385,471} In the setting of a viral infection, allergic disease, or exposure to cigarette smoke, bacteria spread from the nasopharynx to other sites within the respiratory tract and produce symptomatic disease.^{68,323,418}

Pathogenesis of Invasive Disease

After mucosal colonization with *H. influenzae* type b and other potentially invasive strains has been established, dissemination may occur from the upper respiratory tract mucosa to the bloodstream and then elsewhere in the body.³⁶³ The incidence of invasive disease is a small fraction of the carrier rate for *H. influenzae* type b.²⁹⁸ When dissemination does occur, the organism appears to invade the mucosa by separating the apical tight junctions of the columnar epithelium and moving intercellularly.⁴¹¹ The resulting bacteremia initially is low in concentration but steadily increases over the course of hours.³¹⁹ The dynamics between bacterial proliferation and clearance is influenced by antibody, complement, and phagocytes, all of which have an effect on the magnitude of the bacteremia.⁴⁶⁸ The polysaccharide capsule of Hib is antiphagocytic and a major virulence factor. In the absence of ant capsular antibody, bacteremia increases steadily over a period of hours.¹⁶⁹ When the bacterial concentration exceeds 10⁴ organisms per milliliter, metastatic seeding occurs, especially to the meninges through the choroid plexus. Although meningitis is the most frequently recognized manifestation of invasive Hib disease, other potential metastatic sites include the lungs, joint synovium, pleura, peritoneum, and pericardium.^{50,431}

The pathogenic events that lead to pneumonia, cellulitis, and epiglottitis are less well understood, even though these invasive infections are associated with bacteremia. Presumably, pneumonia occurs after the aspiration of a critical number of virulent organisms, epiglottitis involves focal infection of the epiglottis, and cellulitis occurs by secondary seeding of deep subcutaneous tissues through the bloodstream.¹⁴⁸ With all forms of invasive Hib disease, invasion of the bloodstream occurs as a primary or secondary event.

Viral interactions enhance the pathogenesis of Hib.^{309,423} Influenza virus infection reduces neutrophil chemotaxis, bacterial killing, systemic macrophage function, the number of circulating T cells, T-cell blastogenesis, and expression of delayed cutaneous hypersensitivity.^{1,2,78} Reduced bacterial killing may result from a defect in phagosome-lysosome fusion, a defect that is maximal 5 to 7 days after viral infection and inoculation of Hib.

Meningitis

Bacteremia precedes the development of meningitis, except for rare situations in which direct extension of infection from adjacent sinuses or an ear infection occurs. Data from experimental studies of infant rats and infant monkeys support this hypothesis.²⁸⁴ The magnitude and duration of bacteremia are probably the primary determinants of invasion of the central nervous system (CNS). After a critical bacterial concentration is exceeded in blood, Hib appears to enter the CNS through the choroid plexus.⁴⁰⁴

This theory of CNS invasion is supported by several facts: The earliest histopathologic lesion seen in the CNS is choroid plexitis, the choroid plexus is one of the foci seeded from the bloodstream, and bacterial density early in infection is greater in the lateral cerebral ventricles than in other CSF compartments.⁴⁰⁴ Pulse-chase experiments using tracer strains show that organisms enter the CSF through the choroid plexus and that inflammation of the choroid plexus is a uniform feature of meningitis. Subsequently, organisms infect the CSF and the arachnoid villi of the leptomeninges and cause blockage of CSF return, thereby increasing bacterial density and CSF pressure.⁴⁰⁴ The magnitude of CSF bacterial density correlates with the severity of clinical illness.^{117,375} Egress of CSF from the subarachnoid space is by flow through the subarachnoid villi, and bacterial density in CSF can be increased or decreased by manipulating CSF egress, which occurs in meningitis by inflammatory responses. The inflammatory response of the choroid plexus is followed by pachymeningitis, which also inhibits CSF reabsorption and increases pressure. Phlebitis of the cerebral blood vessels and thrombosis can occur. All these events contribute to decreased blood flow to the cortex. The resulting increased bacterial density, inflammation, edema, cranial nerve damage, and overall increased CSF pressure are responsible for the morbidity and mortality associated with meningitis.^{99,116,404} Parenchymal invasion of the brain rarely occurs.

IMMUNOLOGY

Resistance to *H. influenzae* infection depends on successful integration of a wide variety of host defenses, including mucosal factors that prevent the organism from attaching and penetrating the respiratory epithelium^{238,405,409}; activation of the alternative and classic complement pathways, which leads to killing of the organism and initiation of other inflammatory responses^{410,474}; induction of antibody formation^{159,163}; phagocytosis and killing by macrophages and polymorphonuclear cells in tissues, the circulation, and the reticulo-endothelial system^{35,303,478}; and cell-mediated immunity.¹⁰⁰ Assessing the role of each of these immunologic mechanisms independently or determining which mechanisms are most important in host defense is difficult.

Although antibodies are not the sole defense against bacteremia, it has been the research emphasis of vaccine development.¹⁵⁹ The goal has been to induce antibodies that are bactericidal, opsonophagocytic, and ultimately protective. Usually only antibody is measured in these studies, but other immune factors are induced and probably play important roles in protection.

Anticapsular Antibody

Initially, antibody activity was assessed by measuring agglutinin and bactericidal titers of serum. In 1933, Fothergill and Wright¹³⁰ suggested that bactericidal activity was responsible for immunity to Hib meningitis and that acquisition of this immunity correlated with the age of the individual. Although antibodies to several surface antigens of *H. influenzae* play roles in conferring immunity to Hib,³⁹² antibody to Hib capsular polysaccharide appears to be of primary importance.³⁵⁹ Newborns and young infants are at low risk for infection, presumably because they have maternally acquired antibody. Young children at highest risk of acquiring disease have low or undetectable levels of antibody, whereas older children at lower risk have higher antibody levels. By 5 years of age, most children have naturally acquired anticapsular antibody that appears to provide protection,^{168,380} although natural exposure also induces antibodies to outer membrane proteins (OMPs), LPS, and other surface antigens of the bacteria that contribute to natural immunity. The evidence that anticapsular antibodies protect humans from the acquisition of invasive Hib disease is considerable. They activate complement,^{410,474} are opsonophagocytic³¹² and bactericidal,^{130,312} and protect animals from lethal Hib challenge.⁴¹⁴ Passive prophylaxis with serum preparations containing anticapsular antibody protects agammaglobulinemic patients³⁵⁹ and high-risk children from the acquisition of invasive Hib disease.³⁶⁹ In the pre-antibiotic era, immune serum was an effective therapy for Hib disease.^{6,339} However, the most compelling evidence for the protective efficacy of PRP antibody is the clinical protection achieved in older children vaccinated with purified PRP vaccine³²⁶ and younger infants immunized with Hib conjugate vaccines.^{258,327} Induction of antibody to Hib polysaccharide is the immunologic basis of all Hib vaccines.

A precise minimal level of anti-PRP antibody that is protective has not been established.¹⁵⁹ Data from passive protection of agammaglobulinemic children, challenge experiments in infant rats, and studies of naturally acquired antibody levels in healthy individuals of various ages suggest that the minimal serum concentration of anti-PRP antibody that provides protection ranges from 0.05 µg/mL in animals³⁸¹ to 0.15 to 1.00 µg/mL in humans.^{213,326} These estimates are crude and do not take into account the different functional properties of different immunoglobulins.^{163,253} or the contribution of antibodies to other Hib antigens.

Antibody levels decline over time, and a given peak level may not reflect levels at the time of exposure, which would predict long-term protection better.^{14,326} In a Finnish PRP vaccine trial, an antibody level greater than 1.0 µg/mL 1 month after immunization correlated with clinical protection for a minimum of 1 year.³²⁶ However, this antibody level may not be extrapolated readily to the immunogenicity data evaluated in different studies or with different Hib conjugate vaccines.

Class- and Subclass-Specific Antibody

Several studies have shown variable immunoglobulin class, isotype, idiotype, and immunoglobulin G (IgG) subclass responses to PRP polysaccharide after natural Hib exposure, disease, and immunization.^{214,381} Most individuals respond with IgG antibodies after receiving PRP immunization, although some children have predominantly IgA or IgM responses.²¹⁴

Schreiber and associates³⁸¹ showed that IgG antibody is bactericidal, opsonic for polymorphonuclear leukocytes in the presence of complement, and protective for animals. IgM antibody is equally protective and more bactericidal than IgG in the presence of complement, but it opsonizes poorly. IgA antibody is not bactericidal, opsonic, or protective for animals. Some researchers have hypothesized that IgA-specific antibody blocks the activity of other more functional antibodies and thereby may depress immunity.³⁰¹

Data from experiments in mice and humans suggest that polysaccharide antigens induce restricted IgG subclass responses.³⁵⁷ The findings of increased susceptibility to Hib disease in IgG subclass-deficient patients (predominantly IgG2 and IgG4 deficiencies)^{321,383} and the low levels of IgG2 in children younger than 2 years of age³⁸⁹ suggest that differences exist in the role of subclass-specific anticapsular antibodies. In adults, natural exposure or immunization with PRP vaccine results in a predominantly IgG2 subclass response.³⁴⁸ In children, IgG1 and IgG2 antibodies develop after PRP immunization, but IgG1 antibodies predominate after immunization with Hib conjugate vaccines.^{11,189,211}

Human anti-PRP antibodies express predominantly κ light chains⁴²⁶ and may be grouped as a few restricted clonotypes. These clonotypes and antibody specificities have been characterized by idiotype analysis^{251,254,397} and amino acid sequencing of the immunoglobulin light chain.⁴²⁶ Individuals of different ages produce different proportions or repertoires of antibody.²⁵² Some differences in binding specificity and affinity have been described for the different anti-PRP antibodies,^{253,254,377} but whether the antibodies have different degrees of protective potency or are substantially different in proportion in individuals given different vaccines is not clear.

The role of mucosal immunity in killing Hib or inhibiting adherence or penetration of the mucosa is understood poorly, although studies of secretory IgA antibody to the Hib capsule have been conducted.^{335,336} Moreover, Hib strains produce IgA proteases that can inactivate mucosal antibody.^{120,286,296} The observation of reduced carriage of Hib in children given Hib conjugate vaccines suggests that mucosal immunity may be important in reducing transmission of the disease.^{121,181,198,300,316}

Genetic Factors

Compared with protein vaccines, the immune responses to most polysaccharide antigens vary and can be influenced by genetic factors. Several studies have shown associations between the immune responses to PRP vaccine and genetically determined factors such as red cell antigens, human leukocyte antigen, and immunoglobulin allotypes.^{10,165,388,470} However, because many factors influence immunogenicity, whether these associations have relevance is not known, and establishing controls for them is difficult. The antibody differences may or may not be clinically important. No single genetic relationship regulating susceptibility or the immune responses to polysaccharide antigens has been demonstrated convincingly.

Complement

The importance of complement components in host defense against Hib is substantiated by elimination of the bactericidal activity of serum by heat, the susceptibility of complement-depleted animals to Hib disease, and the increased susceptibility of patients with specific congenital complement deficiencies.^{85,410,474} Hib can activate both the classic and alternative complement pathways,^{85,410} thereby initiating opsonophagocytosis and cell killing and eliciting other inflammatory responses. Whereas the alternative pathway probably is most important early in the course of infection in a nonimmune host, the antibody-dependent classic complement pathway is more likely to predominate as a defense mechanism at a later stage of infection.⁴⁷⁴

Encapsulated and unencapsulated organisms activate complement, underscoring the importance of noncapsular antigens in host defense.^{302,303,478} Although the Hib capsule is a poor activator of the alternative complement pathway, antibody to the capsule activates the classic and alternative pathways.⁴¹⁰ Other cell wall antigens activate the alternative pathway, and antibody to these antigens activates the classic pathway.^{85,410,474} In this way, antibodies to capsular and noncapsular antigens activate the complement system, primarily through the classic pathway. Activation of the terminal complement components mediates the bactericidal activity of serum.

Careful studies have explored the contribution of LPS structure to the susceptibility of *H. influenzae* to complement-dependent serum bactericidal activity.^{122,172,256,465} Phase-variable structural modifications to the core LPS structure, including additions of phosphorylcholine,^{72,466} sialic acid,³⁸⁷ and other carbohydrate moieties,^{105,235,481} influence the susceptibility of these organisms to complement-mediated killing. Related studies in animal models of infection have demonstrated the importance of these phase-variable LPS modifications to disease pathogenesis in vivo.^{46,122,200,234,432}

Work by Hallstrom and Riesbeck focused on the ability of *H. influenzae*, particularly nontypeable strains, to modulate activation of the complement cascade by interacting with human complement regulatory proteins.¹⁷⁷ In the presence of human serum, nontypeable *Haemophilus influenzae* are able to bind the C4B binding protein,¹⁷⁵ the human complement inhibitor factor H,^{179,233} and vitronectin.^{178,400,415,416} The presence of these proteins on the bacterial surface protects the organisms against complement-mediated attack and contributes to the survival of *Haemophilus influenzae* in the presence of human serum and serum components.¹⁷⁶

Phagocytosis

Opsonization leading to phagocytosis and killing of *H. influenzae* is an important determinant of host defense.^{302,303,414,477,478} Impairment of phagocytic function or a reduction in the number of phagocytes results in increased susceptibility to disease, as does loss of the spleen or impairment of its function (e.g., hemoglobinopathies).^{66,342} The opsonic activity of serum is influenced greatly by the roles of complement and antibody. Opsonization and phagocytosis of Hib appear to depend on IgG binding, antibody activation of the classic complement pathway with deposition of C3b on the bacterial surface, and direct bacterial activation of the alternative complement pathway.³¹⁴ Relatively little is known about direct cell-mediated killing of *H. influenzae*.¹⁰⁰

EPIDEMIOLOGY

Haemophilus influenzae Type b

Humans are the only natural host for *H. influenzae*, and asymptomatic nasopharyngeal carriage, usually by unencapsulated strains, is a common finding.^{113,151,268,347} In the era before widespread use of Hib conjugate vaccines, nasopharyngeal acquisition of Hib strains was common, increased after infancy, and persisted for weeks to months. Most children were colonized at some time during the first 5 years of life.²⁶⁸ Colonization rates greater than 70% occurred after recent exposure in closed populations, such as among family members or childcare center contacts of a patient with disease.²⁹⁸ Person-to-person transmission occurred through respiratory droplets, and fomites also played a role. As Hib conjugate vaccine administration has become part of the routine infant immunization schedule in many countries, there has been an associated and pronounced drop in the rate of nasopharyngeal carriage of Hib strains.^{181,198,250,299,316,422}

Before the development of immunization, invasive Hib disease was a leading infectious disease problem worldwide that affected primarily the young^{454,469,473} (Table 133.2). Hib strains were responsible for more than 95% of invasive *H. influenzae* infections in children. According to population-based studies, an estimated 20,000 to 25,000 people acquired invasive Hib disease annually in the United States, 85% of which occurred in children younger than 5 years of age.⁵⁰ The incidence of Hib meningitis and all invasive Hib disease was 40 to 69 cases and 67 to 130 cases per 100,000 children younger than 5 years, respectively. Invasive Hib disease developed in an estimated 1 per 200 children in the United States during

^aAnnual incidence per 100,000 children younger than 5 years. NA, not available. Modified from Vadheim CM, Ward JI. Epidemiology in developed countries. In: Ellis RW, Granoff DM, eds. *Development and Clinical Uses of Haemophilus b Conjugate Vaccines*. New York: Marcel Dekker; 1994:231–45; Bijlmer HA. Epidemiology of *Haemophilus influenzae* invasive disease in developing countries and intervention strategies. In: Ellis RW, Granoff DM, eds. *Development and Clinical Uses of Haemophilus b Conjugate Vaccines*. New York, Marcel Dekker; 1994:247–64.

the first 5 years of life.⁷⁵ Hib pneumonia was estimated to cause as many as 15% of cases of ambulatory pneumonia in children younger than 6 years old, but the true incidence was unknown because microbiologic diagnosis is difficult.

Overall, the incidence of Hib disease in the prevaccine era was similar to that of paralytic poliomyelitis during its peak epidemic years before immunization. A bimodal seasonal pattern had been observed in several studies, with one peak occurring between September and December and a second peak between March and May.^{352,469} The attack rate of Hib was slightly higher among boys.²⁶⁰

The widespread use of Hib conjugate vaccines altered the epidemiology of invasive Hib disease dramatically (Fig. 133.1).²⁵⁸ The first Hib conjugate vaccine was licensed in the United States in 1987 for use in children 18 months or older.⁴⁸ Subsequently, decreases in the incidence of Hib disease were seen among older children and unexpectedly among unimmunized infants and children. This finding was attributed to a direct effect of vaccination on nasopharyngeal carriage, which decreased the environmental burden of Hib infection and ultimately decreased transmission of disease. In late 1990, Hib conjugate vaccines were approved for use in infants beginning at 2 months of age, which heralded a dramatic decline in the incidence of invasive Hib disease in all children.⁴⁸ In populations in which immunization rates are high, the development of invasive Hib disease has been eliminated almost completely.^{229,258}

Some population-based studies of the incidence of *H. influenzae* disease have been conducted outside the United States, primarily in Western Europe, and they showed an incidence approximately one third to two thirds that in the United States.^{328,368,407} The incidence of Hib disease is especially high among certain ethnic groups, including Aboriginal children in central Australia,^{182,198} Navajo Native Americans, Native Alaskans, and Apache, Yakima, Athabaskan, and Canadian Native Americans.^{249,258,462,483} *H. influenzae* appeared to rank as a leading cause of bacterial meningitis in several developing countries.^{8,406,457,482} As seen in the United States, a substantial reduction in Hib disease has occurred with the implementation of widespread vaccination programs.^{193,395}

Children between the ages of 6 and 18 months are at highest risk for invasive Hib disease²⁶⁰; however, the age distribution of specific clinical syndromes of the disease varies. The peak incidence of Hib meningitis occurs in children 6 to 9 months of age and declines markedly after 2 years of age.^{134,425} Hib cellulitis tended to occur during the first year of life, whereas epiglottitis occurred in unimmunized children older than 2 years of age. Invasive *H. influenzae* disease was much less common in adults because of the development of protective antibodies over time, but it occurred more frequently in immunocompromised patients. Nonetheless, Hib caused pneumonia and meningitis in adults,^{114,330} and

FIG. 133.1 Incidence of *Haemophilus influenzae* type b (Hib) invasive disease per 100,000 people and the percentage of *H. influenzae* (Hi) isolates serotyped for children younger than 5 years in the United States between 1990 and 2000. (From Centers for Disease Control and Prevention. Progress towards elimination of *Haemophilus influenzae* type b invasive disease among infants and children—United States, 1998–2000. *MMWR Morb Mortal Wkly Rep* 2002;51:234–37.)

disease caused by other serotypes and nontypeable strains, especially pneumonia, otitis media, bronchitis, and sinusitis, are common findings in all age groups.^{79,80,258,346} Most adults in whom invasive *H. influenzae* disease develops were not immunized as children and have an underlying condition such as chronic obstructive pulmonary disease, human immunodeficiency virus (HIV) infection, alcoholism, pregnancy, or malignancy.^{114,346,448}

The development of invasive Hib disease in a given individual is the consequence of a complex interaction of a variety of factors, including the risk of exposure, the characteristics of the organism, and the host.¹³² In populations with a high incidence of disease, such as Native Americans, the age-specific incidence peaked in a younger age group (<6 months), presumably because of early or intense exposure to Hib at home or in the community.²⁵⁵ Several factors that may reflect environmental exposure to the organism, such as household size,¹⁶⁰ crowding,⁴⁴¹ childcare attendance,^{76,196} low family income,^{28,133,134} and low parental education level,^{133,134} are risk factors for the acquisition of disease, whereas breastfeeding appears to be protective.³³¹ Several underlying medical conditions are associated with an increased risk for the acquisition of Hib disease, including HIV infection,^{60,376} sickle cell anemia,³⁴² asplenia or splenectomy,⁶⁶ antibody¹¹⁵ and complement deficiency syndromes,¹²³ and malignancy.⁴⁶⁷

Although the direct contagiousness of invasive Hib disease is limited, small outbreaks and direct secondary transmission of disease can occur.^{56,459,460} Numerous studies have estimated the risk of developing secondary disease in household contacts in the 30 days after the onset of disease in an index case. Overall, the attack rate for contacts of all ages in the prevaccine era was 0.3%, which represents a risk approximately 600-fold higher than the age-adjusted risk for the general population.^{56,459} However, attack rates varied inversely with age, with children younger than 4 years being at greatest risk. Among household contacts, almost two thirds of secondary cases occurred within the first week after the onset of disease in the index patient.⁴²⁵ Controversy exists about the degree of risk for the development of secondary Hib disease in childcare center contacts exposed to a child with invasive Hib disease. The risk for unimmunized children younger than 2 years of age ranged from 0% to 3.2%,^{28,318} whereas for those older than 2 years, it was less than 1%.

A concerning trend several years ago was the reappearance or persistence of Hib disease in highly immunized populations.^{24,198,227,258,402} The factors contributing to these problems are still the subject of debate, but with the reemergence of Hib disease in the United Kingdom in the late 1990s, attention focused on the lack of a booster dosing of infants as part of the regular immunization series and the decreased immunogenicity of combination vaccines in which the Hib conjugate vaccine

was combined with acellular pertussis vaccine components.^{227,274} The Alaskan experience raised different concerns,⁴⁰² but unique characteristics of Hib nasopharyngeal carriage in the rural population and variability in the antibody response of young infants to different Hib vaccines appeared to explain persistent Hib disease in the native Alaskans population.^{258,401,402}

Non-type b Encapsulated *Haemophilus influenzae*

Haemophilus influenzae expressing one of the five non-type b capsular types are also carried in the nasopharynx of a small percentage of the population.^{87,268} With the success of the Hib conjugate vaccine in preventing invasive disease caused by type b organisms, there was initial concern that disease caused by other encapsulated strains might become more prevalent.⁴⁸ Several clusters of invasive disease caused by *Haemophilus influenzae* type a have been reported over the past decade,^{4,52,53,208,355} along with occasional cases of disease caused by other serotypes.^{206,229,317,366} However, surveillance studies for the most part have failed to document a sustained increase in the incidence of disease caused by non-type b serotypes after introduction of the Hib conjugate vaccines.^{206,229,258,271} These data suggest that the concern about serotype replacement may be more theoretical than real.

Nontypeable *Haemophilus influenzae*

Asymptomatic colonization of the mucous membranes of the upper respiratory tract by nontypeable *H. influenzae* strains occurs in 60% to 90% of young children.²²⁴ Infants often become colonized with nontypeable *H. influenzae* early during the first year of life.¹¹¹ Nasopharyngeal colonization is a dynamic process characterized by relatively rapid turnover of individual strains and often by simultaneous carriage of several distinct clones.^{30,87,113,226,382} With increasing age, nasopharyngeal carriage of nontypeable *H. influenzae* becomes less common, but it still occurs in a significant percentage of the population.^{224,382} Nontypeable *H. influenzae* are sometimes associated with invasive disease,^{79,81,106,393,448} but they are a much more common cause of mucosal surface infections such as otitis media, sinusitis, bronchitis, and occasionally pneumonia.^{240,289,295,334}

CLINICAL MANIFESTATIONS

Bacteremia

Occult bacteremia (i.e., not associated with a primary focus of infection) is not a common occurrence with Hib, but bacteremia does precede essentially all invasive Hib infections. In the prevaccine era, Hib was the second leading cause, after *Streptococcus pneumoniae*, of occult bacteremia primarily affecting children 6 to 36 months of age.¹⁵ Most children initially have fever and peripheral leukocytosis. Unlike some cases of *S. pneumoniae* bacteremia, the condition is not benign. In approximately 30% to 50% of children with occult Hib bacteremia, a focal infection such as meningitis, pneumonia, or cellulitis develops.^{83,219}

Meningitis

Meningitis is the most serious manifestation of invasive Hib disease, but no clinical feature differentiates Hib meningitis from other causes of bacterial meningitis in children.¹¹⁶ The onset of disease can be fulminant,¹⁹⁷ but more commonly the signs and symptoms are nonspecific (particularly in young infants) and may include irritability, fever, lethargy, poor feeding, and vomiting. Children younger than 18 months often do not have nuchal rigidity. Older children are more likely to have findings of headache, photophobia, and meningismus. With fulminant Hib meningitis, very rapid neurologic deterioration may occur with increased intracranial pressure, seizures, coma, and respiratory arrest.¹¹⁶ Between 10% and 20% of children with meningitis have other foci of infection, such as cellulitis, arthritis, or pneumonia,^{7,125} and essentially all have concomitant bacteremia.

CSF examination typically reveals a pleocytosis (mean, 4000–5000 white blood cells/ μ L) with a predominance of polymorphonuclear leukocytes.⁹⁹ Approximately 75% of patients have hypoglycorrhachia, and about 90% have an elevated CSF protein concentration. Eighty percent of meningitis cases caused by Hib will have a positive CSF Gram stain. As with other types of bacterial meningitis, previous antimicrobial therapy significantly decreases the concentration of Hib

organisms in the CSF and diminishes the sensitivity of Gram staining.³⁸ Previous treatment does not affect the total blood cell count and differential, glucose concentration, or protein level substantially, permitting a diagnosis of meningitis. In more than 90% of cases, capsular antigen can be detected in CSF or serum.⁴⁶³ Anemia, leukocytosis, thrombocytosis, and thrombocytopenia also are observed frequently.¹¹⁶

Complications of Hib meningitis include seizures, cerebral edema, subdural effusions or empyema, inappropriate secretion of antidiuretic hormone, cortical infarction (often manifested by focal neurologic abnormalities), cerebritis, intracerebral abscess, hydrocephalus, and rarely, cerebral herniation.^{43,99,116,341} Computed tomography and magnetic resonance imaging of the head should not be performed routinely for Hib meningitis, but these studies may be helpful to explore focal neurologic findings or if the clinical course becomes complicated. Small subdural effusions are common findings but are not usually of clinical significance.¹¹⁶

Even with prompt intensive care, the mortality rate for Hib meningitis is approximately 5%, and significant long-term morbidity, including sensorineural hearing loss, delay in language acquisition, developmental delay, gross motor abnormalities, vision impairment, and behavior abnormalities, may occur in 15% to 30% of survivors.^{98,99,116,341,428} A substantial proportion of such abnormalities may resolve over time, emphasizing the need for long-term monitoring of these patients.¹¹⁶

Pneumonia

Hib pneumonia is clinically indistinguishable from other bacterial pneumonias.^{149,452} Most patients have a preceding upper respiratory tract infection, fever, and cough accompanied by peripheral leukocytosis with a predominance of polymorphonuclear leukocytes. Radiologically, Hib pneumonia may be segmental, lobar, interstitial, or diffuse, and many cases have evidence of pleural or pericardial involvement on radiographic examination. Cavitation and pneumatoceles are rare occurrences but have been reported.^{13,67} Computed tomography or magnetic resonance imaging can be useful adjuncts to the evaluation of complicated disease caused by Hib.⁷⁴

Blood, pleural fluid, tracheal aspirate, and lung aspirate cultures are positive in 75% to 90% of cases. Detection of capsular polysaccharide in pleural fluid, serum, or urine can establish the diagnosis, particularly if antimicrobial therapy had been instituted previously. Although fever may persist for several days while the patient is receiving adequate therapy, uncomplicated Hib pneumonia rarely is associated with long-term pulmonary dysfunction. In the developing world, in addition to disease caused by Hib, pneumonia caused by nontypeable *H. influenzae* is a continuing problem that is associated with significant morbidity and mortality.^{140,192,239}

Epiglottitis

Acute upper airway obstruction caused by Hib infection of the epiglottis and supraglottic tissues occurred in the prevaccine era primarily in children 2 to 7 years of age.^{34,275} Its onset usually is abrupt, with high fever, sore throat, dysphagia, and sepsis. Antecedent upper respiratory tract infection with cough occurs in approximately 50% of patients.^{49,248} The child may drool because of an inability to swallow oropharyngeal secretions, and progressive respiratory distress with tachypnea, stridor, cyanosis, and retractions may develop over a period of hours. The child usually is agitated and may sit forward with the chin extended to maintain an open airway. In children younger than 2 years, Hib epiglottitis may manifest in an atypical fashion, with low-grade fever and a cough suggesting croup.²⁴⁸

The most important aspect of the management of a child with epiglottitis is maintenance of a patent airway. Nasotracheal intubation is preferable to tracheostomy because it is equally effective, is not permanent or disfiguring, and has fewer inherent risks.³⁴ Between 70% and 90% of patients with epiglottitis have positive blood cultures; tissue for culture of the inflamed epiglottis should be obtained only after the airway has been secured. A lateral neck radiograph revealing dilation of the hypopharynx and the thumbprint sign (i.e., swollen epiglottis)⁴⁵ can be helpful if the clinical findings are subtle, but in most cases, diagnostic studies should not delay intubation and direct inspection

of the epiglottis in controlled surroundings. The mortality rate is 5% to 10% and is almost always related to abrupt airway obstruction.

Joint Infection

Before the routine use of Hib conjugate vaccines, Hib was the leading cause of septic arthritis in children younger than 2 years of age.¹²⁵ It affects a single large joint at the knee, ankle, elbow, or hip in more than 90% of cases. Contiguous osteomyelitis occurs in 10% to 20%.^{125,236}

No feature clearly distinguishes septic arthritis caused by Hib from that of other bacterial causes. Patients initially are febrile, and more than two thirds have decreased range of motion, local warmth, and swelling.^{88,125,236} Usually, pain, swelling, and erythema of the involved joint are preceded by a nonspecific upper respiratory illness. The clinical features may be subtle, with only decreased range of motion of the joint or abnormal gait as the initial finding. Hib capsular antigen concentrations are very high in the infected joint fluid of children with septic arthritis, and rapid detection of antigen is useful diagnostically.

Septic arthritis of the hip requires surgical drainage. Resolution usually is rapid, but long-term cartilage damage may result from Hib arthritis despite adequate therapy.⁴²⁸

Cellulitis

Cellulitis is a relatively uncommon form of Hib disease and was seen in the prevaccine era almost exclusively in children younger than 2 years of age. Most cellulitis (74%) is located in the cheek (i.e., buccal cellulitis), periorbital region, and neck⁸⁸ and rarely on the extremities. Facial cellulitis occurs most commonly in infants and manifests as acute fever and a unilateral, raised, warm, tender, and indurated area that may progress to a violaceous hue, although this finding is not unique to Hib disease.⁴³⁰

Aspirate cultures of the point of maximal swelling usually yield the organism, and bacteremia is a typical finding.^{126,191} A secondary focus (including meningitis) may occur in 10% to 15% of patients.²⁷ Orbital cellulitis usually is a complication of ethmoid sinusitis and consequently can be caused by non-Hib strains. An etiologic diagnosis can be established by blood culture or aspiration of subcutaneous tissues.

Antibiotics always are indicated. The need for surgical drainage depends on the degree of involvement of the tissues within the orbit.

Pericarditis

Hib pericarditis usually is a complication of adjacent pneumonia and is characterized by fever, an ill appearance, respiratory distress, and tachycardia.^{65,101,356} The radiographic or clinical diagnosis can be confirmed by two-dimensional echocardiography⁴⁷⁹ and may be suggested by finding capsular polysaccharide in serum or pericardial fluid or in Gram-stained pericardial fluid. Cultures of pericardial fluid are positive in more than 70% of cases.⁸⁸

Early drainage is an important part of the management of this illness. Early pericardectomy or pericardiostomy is preferred over repeated pericardiocentesis.^{281,356}

Neonatal Disease

H. influenzae causes 2% to 8% of neonatal early-onset sepsis.^{57,79,187} Most of these cases are caused by nontypeable strains, most of which are concordant with those isolated from the maternal genital tract.⁴⁵⁵ The precise pathogenesis is unknown, but neonatal disease often is associated with prematurity, low birth weight, premature rupture of membranes, and maternal chorioamnionitis; several cases have occurred after cesarean delivery, suggesting in utero transmission.³⁶⁴ Clinical manifestations include pneumonia, bacteremia, and conjunctivitis. More than two thirds of neonatal *H. influenzae* disease occurs on the first day of life, with an overall mortality rate of 55%.¹³⁷

Other Invasive Infections

Other invasive Hib infections include endophthalmitis,⁴²⁷ CSF shunt infections,^{242,353} necrotizing fasciitis, pyomyositis,³⁰⁸ peritonitis,^{71,136} scrotal abscess,²⁴⁷ brain abscess,¹¹⁹ polyserositis,²⁷⁷ tenosynovitis,³⁰⁷ epididymitis,¹⁶⁷ lung abscess,²⁴⁶ periappendiceal abscess,²⁷⁰ and bacterial tracheitis.⁵⁸ Invasive disease also may be characterized by fever alone, fever with petechiae, or fever of unknown origin.^{51,446}

Diseases Caused by Non-Type b *H. influenzae*

Respiratory tract infections associated with nontypeable *H. influenzae* are a major cause of morbidity and mortality in developed and non-industrialized nations.^{81,239,454} Previously, invasive disease caused by nontypeable *H. influenzae* was rare and typically associated with underlying medical conditions such as prematurity, malignancy, cystic fibrosis, asthma, CSF leakage, CNS shunts, congenital heart disease, lymphoproliferative disorders, and immunoglobulin deficiency.^{112,144,313} With a decline in the rate of infections caused by Hib, other *H. influenzae* serotypes such as types a, e, and f and nontypeable strains have become relatively more common causes of mucosal surface infection and invasive disease,^{53,81,206,229,232,439} although it is unclear whether the absolute incidence of disease has increased.²⁵⁸

There have been several reports of invasive disease clusters caused by *H. influenzae* type a.^{4,52,53,180,439} One suggested that an IS1016-bexA deletion in the chromosome of the recovered type a strains, a deletion similar to that in many Hib strains,²²² might be a marker for more virulent type a clones.⁴

Other serotypes have also been reported as causing cases of non-type b invasive disease.^{206,229,258,317} Urwin and associates⁴⁴⁰ identified 91 cases of invasive *H. influenzae* type f disease in a multistate area over the course of a 6-year period. The incidence of invasive type f disease was 0.5 cases per 1 million people in 1989 and 1.9 cases per 1 million people in 1994. Among children, pneumonia and meningitis each accounted for 40% of the total cases. The overall mortality rate for type f *H. influenzae* disease was 21% for children. Serotype f also has been reported as a cause of endocarditis¹³⁵ and septic arthritis¹⁵³ in healthy, normal children.

Invasive disease in children caused by nontypeable *H. influenzae* has been reported by several groups.^{81,106,232,448} Heath and associates¹⁸⁶ conducted an active prospective surveillance study of *H. influenzae* infections in the United Kingdom and Republic of Ireland. During the study period (October 1992–December 1998), 102 cases of invasive disease caused by nontypeable *H. influenzae* were reported. Children with nontypeable *H. influenzae* infection were compared with those who had Hib disease. The former were more likely to be younger (16 vs. 22 months) and more likely to have pneumonia and bacteremia ($P < .001$) than were those with Hib disease. In 1998, the incidence of non-type b *H. influenzae* disease among all children younger than 5 years of age in the United Kingdom was 1.3 cases per 100,000, compared with 0.6 per 100,000 children for Hib disease. Most non-type b strains isolated were nontypeable.

Mucosal Infections

Unencapsulated or non-Hib strains cause a variety of mucosal infections, including otitis media, sinusitis, conjunctivitis, and bronchitis.^{217,240,295} Nontypeable *H. influenzae* otitis media has clinical features similar to otitis media caused by other common middle ear pathogens, including fever, symptoms referable to the upper respiratory tract, and nonspecific symptoms such as irritability, vomiting, and diarrhea.²⁴¹ Data suggest that nontypeable *H. influenzae* is the most common cause of acute otitis media and persistent or recurrent otitis media in children who have received the pneumococcal conjugate vaccine.^{39,203,334,472}

Sinusitis caused by nontypeable *H. influenzae* may manifest as common cold symptoms that are persistent or more severe than usual.^{450,451} Older children and adults are more likely to complain of headache and paranasal, dental, or facial pain. Other common symptoms are a daytime cough that may worsen at night or reactive airway disease unresponsive to therapy. Rarely, chronic otitis or sinusitis may result in the development of mastoiditis or a parameningeal abscess.²⁰⁹ Conjunctivitis usually is bilateral and purulent and may occur in outbreaks.^{40–42} Although common, these mucosal infections rarely are life-threatening and are not associated with bacteremia in most cases.

DIAGNOSIS

A high index of suspicion for the possibility of Hib disease must be maintained when evaluating children with appropriate clinical manifestations and findings. The primary criterion for the diagnosis of *H.*

influenzae infection is Gram stain or isolation of the organism from an infected focus (e.g., CSF, pleural fluid, sputum, blood).

Because most invasive Hib disease is associated with bacteremia, blood cultures should be performed for any febrile child with potential Hib disease.²¹⁹ The specimens need to be processed immediately because the organism is fastidious. Although most commercial blood culture media support the growth of *H. influenzae*, the inoculum should be applied, when possible, directly to chocolate agar or a semisynthetic medium containing heme and NAD.^{139,237,329} In liquid medium, growth may not be sufficient to result in turbidity; therefore, for blood cultures, advanced detection systems or subcultures should be performed.²³⁷ Selective media that suppress the growth of gram-positive organisms may increase the recovery of *H. influenzae* from upper respiratory tract specimens.⁶⁴ Identification of an isolate as *H. influenzae* relies on its dependence on heme and NAD.²³⁷

Determination of the capsular type expressed by *H. influenzae* is important for clinical and epidemiologic purposes. Traditionally, this has been performed by slide agglutination with capsular type-specific antisera and suspensions of bacterial organisms.²³⁷ Polymerase chain reaction (PCR) techniques that target the capsular gene locus have been developed that accurately identify strains expressing the six recognized capsular types.^{257,311}

Other techniques that may assist in microbiologic diagnosis include rapid antigen detection, staining techniques, and immunofluorescence.^{207,264,463} These techniques are useful in the context of a patient whose cultures are sterile because of previous antibiotic therapy, or they can confirm the clinical diagnosis before bacterial growth occurs. The three techniques most commonly used in the past for antigen detection were latex particle agglutination (LPA), counterimmunoelectrophoresis (CIE), and coagglutination (CoA). False-positive results on CSF were rare for all three tests but did occur when testing serum and urine. LPA appeared to be the most sensitive of the three tests and is the only one that remains in common use today. False-positive results can occur in the urine of children with nasopharyngeal carriage of the organism or, more commonly, for several days after immunization with Hib conjugate vaccine.⁴⁰⁸

Acridine orange is a fluorescent stain that binds to cellular nucleic acids and may be useful for smaller bacterial concentrations.²¹⁶ Immunofluorescent staining of purulent specimens from patients with partially treated disease also has been useful.⁷³

TREATMENT

Invasive Disease

Bacteremia plays a central role in the pathogenesis of invasive Hib disease, and occult invasion of the CNS always must be considered in the context of any manifestation of Hib infection.^{148,219} Severe Hib disease often is fatal if not treated adequately. Elimination of Hib bacteremia and its complications requires antimicrobial therapy that can penetrate the blood-brain barrier to achieve bactericidal concentrations and is of adequate duration to sterilize the primary and potential secondary foci.

The choice of specific antibiotic therapy must take into account the local antibiotic susceptibility patterns of invasive isolates (Table 133.3). *H. influenzae* resistance to several antimicrobials, including ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, rifampin, and certain second-generation cephalosporins, has been increasing in several areas of the world.^{95,184,354,434}

For proven or suspected Hib meningitis, cefotaxime or ceftriaxone is recommended until the antibiotic susceptibility of the organism is known or an alternative diagnosis is established.^{12,116} Both antibiotics have bactericidal activity against Hib strains, including those that produce β -lactamase, and they penetrate well into infected CSF and are well tolerated. Cefuroxime should not be used for the treatment of *H. influenzae* meningitis because delayed sterilization of CSF may be at least twofold more common than with ampicillin plus chloramphenicol or with the third-generation cephalosporins.^{18,403} Ampicillin, formerly a mainstay of therapy for this infection, should not be used empirically to treat infections caused by Hib because as many as 50% of Hib isolates in the United States are resistant, usually through plasmid-mediated β -lactamase production.^{204,237}

TABLE 133.3 Selected Antimicrobial Agents for Treatment of *Haemophilus influenzae* Infections

Antimicrobial Agent	Total Daily Dose (mg/kg)	Dose Frequency
Parenteral Antibiotics^a		
Ampicillin ^b	200–400	q4–6h
Cefuroxime ^c	100–200	q8h
Cefotaxime	200–225	q4–8h
Ceftriaxone	50–100	q12–24h
Oral Antibiotics		
Amoxicillin ^d	40–90	tid/bid
Amoxicillin-clavulanate	40–90	tid/bid
Trimethoprim-sulfamethoxazole ^d	8 (trimethoprim)	bid
Clarithromycin ^d	15	bid
Azithromycin ^d	10	qd
Cefuroxime axetil	30	bid
Cefprozil	30	bid
Cefpodoxime	10	bid
Cefixime	8	qd
Cefdinir	14	qd

^aOther parenteral agents may be used in special circumstances, but they should not be considered first-line drugs. They include ureidopenicillins, carbapenems, and fluoroquinolones.

^bNot to be used presumptively because of the prevalence of resistant strains.

^cNot to be used for suspected meningitis.

^dDo not use these oral agents if resistance is suspected or prevalent in your area.

Chloramphenicol, another medication that frequently was used in the past to treat Hib disease,^{278,365} is rarely used now because safer antibiotics with greater activity are available. Although adequate bactericidal blood and CNS levels of chloramphenicol can be achieved, even with oral administration,^{118,372} its use requires monitoring of drug levels. Dose-dependent, reversible bone marrow toxicity may occur, particularly in neonates, in patients with liver disease, or in those who require prolonged treatment.²⁷⁸ Idiosyncratic aplastic anemia, a dose-independent complication of chloramphenicol use, is extremely rare.

Cefuroxime has good activity against *H. influenzae* and is useful for empiric treatment of nonmeningitic infections such as pneumonia, periorbital cellulitis, and septic arthritis.⁴⁴⁵ Other parenteral agents that have activity against *H. influenzae* include meropenem, ampicillin-sulbactam, aztreonam, and other third-generation cephalosporins such as ceftazidime.^{237,269} The spectrum of activity of the latter agents is too broad for routine use for pediatric infections in which Hib is an important pathogen.

Children with occult Hib bacteremia need to be reevaluated carefully because focal disease may develop in 30% to 50% of patients who are clinically well.^{83,219} The duration of therapy is determined by the site of infection and the clinical response. Children with uncomplicated Hib meningitis can be treated for 10 days.^{12,116} Children with Hib cellulitis can be switched to oral therapy after several days of parenteral therapy, provided that they have had a satisfactory clinical response and do not have meningitis. Patients with septic arthritis should receive at least 10 to 14 days of therapy,¹²⁵ whereas children with pericarditis, empyema, or osteomyelitis may require longer courses of antibiotic treatment (i.e., 3 to 6 weeks).^{65,125} These patients often can be switched to oral antibiotics after documenting susceptibility, observing a good therapeutic response, and ensuring compliance.

Equally important in the overall management of a child with invasive Hib disease is supportive care. For Hib meningitis, several studies have shown that adjunctive therapy with dexamethasone moderates the inflammatory cascade and may decrease the likelihood of hearing loss.³¹⁵ The recommended dose is 0.6 mg/kg per day given every 6 hours for 4 days, with the first dose administered just before or concurrently with the first antibiotic dose.^{12,315,343} Management of a child with meningitis

requires continuing careful evaluation for complications such as the development of shock, inappropriate secretion of antidiuretic hormone, seizures, subdural empyema, and secondary foci of infection.^{98,99,341} Prolonged fever is a common occurrence, with approximately 10% of children remaining febrile for at least 10 days.¹¹⁶ Repeat lumbar puncture to document sterility of the CSF is not necessary in uncomplicated cases.

In children with epiglottitis, protection of the airway is the most important component of therapy and should be initiated even before the administration of antimicrobials.⁴⁵ Endotracheal intubation or tracheostomy is performed optimally in the operating room by personnel experienced with these procedures in children. Before establishing the airway, care should be taken not to precipitate laryngospasm by attempting to examine the epiglottis or by performing procedures such as venipuncture.^{34,45} Blood should be obtained for culture and intravenous antibiotics initiated as soon as possible after the airway has been secured.

Patients with subdural empyema, pericarditis, or pleural empyema usually require percutaneous or surgical drainage.^{65,99} Infected joint fluid should be aspirated from children with septic arthritis to confirm the diagnosis and reduce pressure.¹²⁵ Repeated aspirations or placement of a surgical drain also may be needed. Infection of the hip requires surgical incision and drainage to decompress the joint; failure to do so may result in avascular necrosis of the femoral head.¹²⁵

Noninvasive Disease

Noninvasive *H. influenzae* infections, usually caused by nontypeable strains, include otitis media, sinusitis, conjunctivitis, bronchitis, and pneumonia. Numerous orally administered antimicrobials are available to treat these infections (see Table 133.3). Despite the increasing prevalence of β -lactamase-producing organisms, amoxicillin remains the drug of choice for empiric treatment of otitis media in most areas because of its low cost and proven safety.^{12,245} Several other antimicrobials with activity against *H. influenzae* are available and include amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, a macrolide such as azithromycin, and second- and third-generation cephalosporins such as cefuroxime, cefpodoxime, and cefdinir.²³⁷ The quinolone antibiotics, such as ciprofloxacin, also are active but are not administered in children routinely for upper respiratory infections. In the context of poor clinical response or isolation of β -lactamase-producing organisms, amoxicillin-clavulanate (Augmentin), cefpodoxime, and cefdinir appear to be the most useful.^{12,245}

Most mucosal infections are treated presumptively without obtaining definitive cultures, and consequently, the duration of therapy and the need for alternative antibiotics are based on assessment of the clinical response. Otitis media usually is treated for 7 to 10 days, and sinusitis should be treated for at least 1 week beyond the resolution of symptoms.^{12,245,450} If resistance is suspected and leads to failure of treatment, an empiric change in antibiotics is indicated.²⁴

PREVENTION

The near elimination of invasive Hib disease in the United States and other countries is a direct result of the routine use of Hib conjugate vaccines and represents a remarkable success story.²⁵⁸ Prevention with hyperimmunoglobulin also is effective in high-risk populations, but it

is costly, has short-lived benefit, and is not licensed for general use.³⁶⁹ Antimicrobial prophylaxis is effective for the prevention of secondary Hib disease, but it represents only a minor proportion of the overall disease burden.^{12,28}

Active Immunization

The first Hib vaccine was the PRP polysaccharide vaccine, which is composed of purified Hib capsular polysaccharide PRP.^{19,361} In 1985, it became the first vaccine to be licensed for the prevention of Hib disease in children older than 18 months of age. Children younger than 18 months of age had inadequate immune responses with PRP vaccination.^{16,212} PRP vaccine has immunologic properties similar to those of some other polysaccharide vaccines, which are considered to be T-cell-independent immunogens.³ The antibody responses are limited and of short duration, particularly in young children, and no booster response occurs with repeated administration of the vaccine. The induced antibody may have reduced functional qualities (i.e., primarily IgM and low avidity).^{358,389}

Licensure of PRP vaccine was based on the findings of a large, randomized clinical trial conducted in Finland in 1974^{325,326} that suggested a protective efficacy of 90% for children who were immunized between 18 and 71 months of age. After licensure of this vaccine in the United States, it became apparent that routine use of the vaccine resulted in efficacy less than that determined in the Finnish vaccine trial (0–88%).⁴⁶¹ This vaccine is mainly of historic significance because its role has been supplanted by development and licensure of the PRP-protein conjugate vaccines.

Hib conjugate vaccines were developed in an effort to enhance immune responses to the PRP antigen. Basic to all conjugate vaccines is the use of a covalently linked (conjugated) immunogenic protein carrier that confers on the PRP polysaccharide hapten recognition by T cells and macrophages and stimulation of T-cell-dependent immunity.^{231,461} Four Hib conjugate vaccines have been developed and evaluated in infants, and all use PRP polysaccharide or oligosaccharides derived from it as the primary immunogen (Table 133.4): PRP-D (i.e., diphtheria toxoid), HbOC (i.e., mutant diphtheria toxin), PRP-OMP (i.e., major OMP of *Neisseria meningitidis* serogroup B), and PRP-T (i.e., tetanus toxoid).

The immune response after administration of Hib conjugate vaccination has several characteristics. It is quantitatively enhanced, particularly in younger infants; repeat administration of vaccine elicits booster responses; and maturation of class-specific immunity with a predominance of IgG antibody and probably enhanced functional properties occurs.

The first Hib conjugate vaccine licensed was PRP-D, but it was less immunogenic than the conjugate vaccines developed subsequently, and it is not currently used in the United States. In children 15 months of age or older who received PRP-D, high antibody concentrations were achieved with a single dose.^{36,189} However, antibody levels greater than 1 $\mu\text{g/mL}$ developed in less than one half of infants, even after receiving three doses.^{92,211} Numerous case-control studies demonstrated that a single dose of vaccine was at least 80% efficacious in preventing disease in children 18 months or older. In infants who received vaccine at 3, 4, 6, and 14 to 18 months of age, the protective efficacy after three doses was 94% in Finland.¹⁰⁸ In contrast, a trial conducted with Native Alaskan infants found no evidence of protection for that high-risk population.⁴⁵⁸

TABLE 133.4 Characteristics of *Haemophilus influenzae* Type b Conjugate Vaccines

Vaccine	Polysaccharide Size	Protein Carrier	Linkage	Trade Name ^a
PRP-D	Medium	Diphtheria toxoid	Protein with 6-carbon spacer	ProHIBIT
HbOC	Small	CRM ₁₉₇ (mutant diphtheria toxin)	PS without a spacer	HibTITER
PRP-OMP	Medium	<i>Neisseria meningitidis</i> outer-membrane protein complex	Protein and PS with bigeneric spacer	PedvaxHIB
PRP-T	Large	Tetanus toxoid	PS with 6-carbon spacer	ActHIB, Hiberix

^aPRP-OMP is also available in combination with hepatitis B vaccine (Comvax), and PRP-T is available in combination with diphtheria-tetanus-acellular pertussis (Pentacel) and MenCY (MenHibrix). The PRP-D and HbOC vaccines are no longer commercially available.

HbOC, Mutant diphtheria toxin; PS, polysaccharide; PRP-D, diphtheria toxoid; PRP-OMP, major outer-membrane protein of *N. meningitidis* serogroup B; PRP-T, tetanus toxoid.

A single dose of HbOC was highly immunogenic in children older than 18 months of age,^{189,259} and after the administration of three doses in infancy, high antibody levels were achieved.^{92,361} Two prospective clinical studies demonstrated that two or three doses of HbOC administered in the first 6 months of life provided a high degree of protective efficacy. In the Kaiser Permanente northern California region population, HbOC was 100% efficacious after two doses administered in infancy.³⁷ The vaccine also was evaluated in Finland in infants who received vaccine at 4, 6, and 14 to 18 months of age, and efficacy was 95% after two doses.¹⁰⁹ Data from a third postlicensure study in infants in Los Angeles County suggested a protective efficacy of 89% after two doses and 94% after three doses.⁴⁴³ Although used for a number of years in the United States, the HbOC vaccine is no longer available for use in children in this country.

PRP-OMP induces an immune response that is less age dependent than the response to the other Hib conjugate vaccines. Adults and children respond to a single vaccine dose with high antibody levels.³⁶² In infants as young as 6 to 8 weeks, a single dose of PRP-OMP induces a good antibody response.⁵⁴ The antibody levels achieved after two doses are higher than those after two doses of any of the other conjugate vaccines,^{54,92} and a third dose does not enhance the response. PRP-OMP was evaluated in a randomized, double-blind, placebo-controlled trial involving high-risk Navajo Native American infants³⁷⁰ who received vaccine at 2 and 4 months of age; an overall efficacy of 95% was reported. Additional data from a population-based, case-control study in Los Angeles County suggested a level of effectiveness similar to that seen for HbOC.⁴⁴²

PRP-T is highly immunogenic in adults and older children,^{69,379} and high concentrations of antibody are achieved in infants with a three-dose immunization series at 2, 4, and 6 months of age.⁹² The protective efficacy of PRP-T was evaluated in two large, prospective, randomized trials that were terminated prematurely because of the licensure of other Hib conjugate vaccines for infants. More than 12,000 infants were enrolled in studies in southern California and North Carolina, and no cases of invasive Hib disease occurred in the vaccinated children compared with five cases in the control groups.^{138,444} Efficacy subsequently was shown in a study in England; after three doses in infancy, the efficacy of PRP-T was estimated to be 100%.⁴⁴ In Finland, during the first 2 years of its general use, more than 100,000 infants were immunized, and only two cases of invasive Hib disease occurred in vaccinees, both after a single dose.

Direct comparisons of Hib conjugate vaccines must be considered in the context of the various study designs, differences in vaccine lots, and different laboratory and statistical methodologies that were used in the clinical trials. Despite these uncertainties, certain principles are evident. First, all Hib conjugate vaccines are safe in infants. Second, PRP-D is the least immunogenic conjugate vaccine. Third, only PRP-OMP induces a good immune response after one dose in young infants, but antibody levels are lower than those induced by multiple doses of HbOC and PRP-T vaccine. Fourth, PRP-OMP, HbOC, and PRP-T appear to be efficacious, but no direct comparison of the protective efficacy of these vaccines has been completed. Mixed administration sequences of Hib vaccines (e.g., PRP-OMP followed by HbOC or PRP-T) may enhance the antibody response,^{157,166} and simultaneous or prior receipt of other non-Hib vaccines may affect the antibody response,^{162,164,244} presumably due to effects of the carrier proteins. Better understanding of the biologic basis for these observations awaits future studies.

Investigation of the feasibility of administering Hib vaccines in combination with other vaccines has been the focus of much research effort over the past 15 years. Early studies by Schmitt and associates³⁷⁸ assessed the impact and effectiveness of DTaP (IPV)-Hib combination vaccines in Germany. Although combination DTaP-Hib vaccines elicited lower anti-Hib titers than separate vaccines, the investigators were able to show that combination vaccines were effective in reducing the incidence of Hib disease.³⁷⁸ Subsequent data from Canada also suggested that a multicomponent Hib-containing combination vaccine was safe and effective in preventing invasive type b *Haemophilus* disease in young children.^{373,374} These studies and others led to the subsequent licensing of a five-component combination vaccine (DTaP-IPV-Hib) that has been approved for use in the primary Hib vaccination series for US children since 2008.^{63,156}

The phenomenal success of the Hib vaccination strategy has been related to the effectiveness of Hib conjugate vaccines in preventing colonization. Fernandez and associates¹²¹ reported that the anti-Hib capsular polysaccharide antibody concentration required to prevent colonization was greater than that needed for protection against invasive disease. Whether concentrations in the range that Fernandez and associates suggested was important (>5 µg/mL) can be achieved and sustained by using conjugate vaccines in all population groups remains a subject of investigation. Studies of some high-risk population groups (e.g., Alaskan natives) have documented that invasive disease is prevented best by the use of PRP-OMP Hib vaccine,^{401,402} at least for the first dose of vaccine, and that even the use of PRP-OMP Hib vaccine in these individuals may not eliminate carriage of the organism in the population.^{94,141} Use of combination vaccines in this population is unlikely to be as effective as use of PRP-OMP Hib conjugate vaccine.^{48,402}

Currently used *H. influenzae* vaccines are based on immunity to the Hib capsule. Antibodies to other components of the bacterium also have been shown to be bactericidal, opsonophagocytic, and protective in animal studies.^{26,31,93,104,173,225,288,292,293,476} Vaccines containing other bacterial antigens could in theory provide supplemental protection against Hib, although this protection does not appear to be necessary in most individuals based on the efficacy of the available Hib conjugate vaccines. Even so, alternative vaccines could provide immunity to non-Hib strains, which are ubiquitous colonizers of the upper respiratory tract of humans.^{113,224}

A problem that must be overcome in the development of these vaccines is the known diversity of many of the candidate vaccine antigens.^{31,145} Because of the known strain-to-strain variation in a number of these antigens,⁹⁷ finding an antigen relevant to all or most strains has been a challenge.^{31,290} Human trials have reported limited success in preventing cases of *H. influenzae* otitis media with a pneumococcal polysaccharide-*H. influenzae* protein D conjugate vaccine,^{344,345,433} and several other candidate vaccine antigens remain the subject of active preclinical research.²⁹¹

Passive Immunization

Although active immunization is preferred for the control of Hib disease, passive immunization has potential utility in some settings: selected high-risk groups with a risk of acquiring disease soon after birth and too young to respond to vaccination (i.e., Eskimos or Native Americans), functionally asplenic patients, immunocompromised patients, and for prevention of secondary disease in households, childcare centers, or institutions.

A human hyperimmunoglobulin from adult Hib-immunized donors called bacterial polysaccharide immunoglobulin has been prepared,³⁹⁴ but it is not commercially available. Pharmacologic studies show that high levels of antibody can be achieved after intramuscular injection, and significant protective efficacy against invasive Hib disease has been demonstrated in Apache children given three doses during the first year of life.³⁶⁹ The use of concurrent active immunization with bacterial polysaccharide immunoglobulin also may be an effective strategy.²⁴³ Another possible approach is maternal Hib immunization¹⁵⁴ to induce transplacental antibody, but questions remain regarding the safety and acceptability of vaccinating pregnant women and the inability to immunize women who do not receive prenatal care.

Impact of *H. influenzae* Type b Vaccination

The impact of widespread vaccination with Hib conjugate vaccine in the United States has been dramatic^{48,258} and has been reproduced in many other countries throughout the world.^{47,127,384,395,417} The decrease in the incidence of disease has exceeded expectations given the estimated proportion of the population completely immunized. In essentially all of these populations, a significant decrease in the incidence of disease was observed among infants before the licensure and recommended use of vaccines in that age group. These findings probably are explained by a reduction in Hib carriage as a result of vaccination^{300,422} and decreased transmission from immunized children to unimmunized young children and infants.

Immunization schedules vary in different countries to parallel immunization practices for other vaccine-preventable diseases. The

age-specific incidence of disease also varies in different countries. Initially in the United Kingdom, the occurrence of disease was such that physicians felt justified to use only a three-dose schedule at 2, 3, and 4 months of age and not to provide a booster dose in the second year of life. This schedule, introduced in the United Kingdom in 1993, appeared to coincide with the reappearance of type b disease in older children observed in the late 1990s.^{17,201,230,227,273,349} The experience emphasizes the importance of giving a fourth dose when children are between 12 and 18 months of age if circumstances permit.

Chemoprophylaxis

Secondary disease accounts for less than 2% of all cases of invasive Hib disease. Chemoprophylaxis can protect susceptible people from acquiring Hib by eliminating Hib colonization in close contacts. Children younger than 4 years have a 600-fold increased risk of acquiring Hib disease after household contact with a case.⁴⁵⁹ Risk also appears to be increased in childcare center settings, but this risk is less well defined.^{158,318} Adults and older children who are colonized can transmit Hib to susceptible children even though they have little risk of acquiring invasive disease themselves.

Antimicrobial agents effective for chemoprophylaxis must achieve bactericidal levels intracellularly and in mucosal secretions. Rifampin, which achieves high concentrations in respiratory secretions,²⁷² is the most effective antimicrobial agent for eradicating Hib from the nasopharynx. Rifampin in a dosage of 20 mg/kg once daily (maximal daily dose, 600 mg) for 4 days eradicates Hib carriage in 95% or more of household^{128,155} or childcare center¹⁶¹ contacts of a case. Cohort studies have shown the effectiveness of rifampin prophylaxis in preventing secondary Hib disease in household contacts and childcare center attendees.^{155,161,261} Antimicrobials effective in the treatment of Hib disease, such as ampicillin, trimethoprim-sulfamethoxazole, erythromycin-sulfisoxazole, and cefaclor, have been ineffective for antimicrobial prophylaxis.¹⁹⁰ They eliminated Hib carriage in less than 70% of culture-positive contacts and are not recommended for chemoprophylaxis.

The US Public Health Service Advisory Committee on Immunization Practices⁴⁸ and the American Academy of Pediatrics Committee on Infectious Diseases¹² recommend rifampin prophylaxis for all household contacts, including adults, and for the index patient (i.e., therapeutic antibiotics do not eradicate Hib from the nasopharynx consistently) if the household has a contact younger than 4 years who is not fully immunized. Prophylaxis should be instituted as soon as possible because the risk of acquiring secondary disease is greatest during the few days after the onset of disease in the index patient and within 2 weeks of the onset of disease. No consensus exists concerning the need for chemoprophylaxis in the childcare setting because of uncertainty about the magnitude of the risk of acquiring secondary Hib disease in this setting. Some investigators recommend chemoprophylaxis if classroom contacts include children younger than 2 years of age, whereas others think that recommendations should be individualized.^{89,318} Virtually all experts recommend prophylaxis if two or more cases of Hib disease have occurred among attendees within 60 days.^{12,48}

In all situations in which the potential for secondary disease exists, this risk should be explained to families, with an emphasis on the importance of seeking prompt medical attention for febrile illnesses. Clinicians should not obtain pharyngeal cultures to determine whether prophylaxis should be administered because doing so only delays the prompt administration of chemoprophylaxis.

CONCLUSIONS

The perspective on *Haemophilus* disease has changed dramatically in recent years. Before the availability of Hib conjugate vaccines, invasive Hib was one of the most important bacterial pathogens of children. It was the leading cause of bacterial meningitis and an important cause of other bacteremic illnesses. The spectrum of illness is broad, morbidity and mortality are significant, and subtleties in making an early diagnosis and instituting appropriate management exist. Because most antibiotic use worldwide is for upper respiratory tract infections, including otitis media and *H. influenzae* causes a significant proportion of these illnesses, it still must be considered a very important pediatric pathogen.

The most important aspect of work on *H. influenzae* has been disease prevention by routine immunization of infants with polysaccharide-protein conjugate vaccines. This achievement is the culmination of more than 100 years of research. Although historically there were many technologic problems and misunderstandings about the organism and its pathogenesis, much has been accomplished. The impact of routine infant immunizations with Hib conjugate vaccines has been dramatic. The public health benefits parallel the eradication of polio and the control of other vaccine-preventable childhood diseases. Widespread Hib immunization virtually has eliminated Hib disease in the United States and in many developed countries where it is used routinely. The degree of disease control exceeded all expectations and is in excess of what the known levels of immunization would have predicted.

Some progress has been made at the preclinical level in the development of vaccines against other *H. influenzae* serotypes and nontypeable strains.²⁹¹ Control of infection caused by these organisms will have an important public health impact, and use of these vaccines may have a role in the health of adolescents and adults. The technologies that led to the development of Hib conjugate vaccines served as a prototype for vaccines to prevent disease caused by other encapsulated bacteria, including the pneumococcus, meningococcus, and group B *Streptococcus*. The lessons learned in the quest to eliminate Hib disease have had important implications in the control of many other bacterial diseases.

Other *Haemophilus* Species (*Ducreyi*, *Haemolyticus*, *Influenzae* Biogroup *Aegyptius*, *Parahaemolyticus*, and *Parainfluenzae*) and *Aggregatibacter (Haemophilus) aphrophilus*

134

Stephen J. Barenkamp

Most serious pediatric infections caused by organisms of the *Haemophilus* genus are caused by *H. influenzae*. However, other *Haemophilus* species can cause disease occasionally. Among the other species that have been reported to cause disease in pediatric and adolescent patients are *H. aegyptius*, *H. ducreyi*, and *H. parainfluenzae*. *Aggregatibacter aphrophilus*, until recently known as *Haemophilus aphrophilus*, is also an occasional cause of infections in pediatric patients. *H. aegyptius* is currently classified as a member of the species *H. influenzae* (*H. influenzae* biogroup *aegyptius*), but given the unique characteristics of this organism and the distinctive illness with which it is associated, it is discussed in this

chapter. Other *Haemophilus* species such as *H. haemolyticus* and *H. parahaemolyticus*, rarely cause illness in the pediatric population,^{12,153} so they are not discussed in detail here. However, *H. haemolyticus* has been the subject of a several reports in the literature because nonhemolytic strains of *H. haemolyticus* are sometimes misidentified as *H. influenzae* unless careful and thorough microbiologic testing is performed.^{142,155,170,215}

Members of the *Haemophilus* genus are gram-negative coccobacillary bacteria that are facultatively anaerobic. They demonstrate optimal growth when they are incubated in a humid atmosphere containing

CO₂, Carbon dioxide; D, differences encountered.

5% to 10% carbon dioxide.^{112,122,154} Most species have fastidious nutritional requirements and require special media, supplements, or both for optimal growth.^{112,122} X factor (hemin), V factor (nicotinamide adenine dinucleotide), or both are required for in vitro growth.¹⁶⁵ Organisms with the “para-” prefix require V factor only. The specific nutritional requirements of *Haemophilus* isolates are among the characteristics used to subclassify these organisms into the different species (Table 134.1).

AGGREGATIBACTER (HAEMOPHILUS) APHROPHILUS

Bacteriology

H. aphrophilus was described first by Khairat¹¹¹ in 1940 in association with a fatal case of endocarditis. He suggested the species name *aphrophilus* because the organism required relatively high concentrations of carbon dioxide for isolation on the usual media. In earlier times, a well-known manifestation of carbon dioxide was the formation of bubbles of gas in fermenting wine (i.e., froth, or *aphros*).^{26,111} Although the organism originally was classified as a *Haemophilus* species because of the growth requirement for X factor, more recent studies suggested that it can grow independent of this factor.^{112,160,213} Given this latter characteristic and based on other more recent analyses,⁵² the organism has now been placed in the genus *Aggregatibacter* and is known as *Aggregatibacter aphrophilus*.^{158,243}

Epidemiology and Pathogenesis

A. aphrophilus is a component of the normal oral flora. Using a selective medium, Kraut and coworkers¹¹⁵ isolated the organism from gingival scrapings and interdental material of one-third of the healthy adults they examined. With respect to disease pathogenesis, it has been suggested that dental disease or manipulation predisposes to transient bacteremia, which results in seeding of distant tissue sites where localized infection subsequently develops.^{26,82,157,160,187} In addition, several case reports of patients with *A. aphrophilus* disease reported an association between human infection and contact with or bites from dogs and cats.^{67,99,157,160,226} However, a causal relationship has been difficult to confirm, and the human mouth and respiratory tract probably are the portals of entry for most infections.

Clinical Manifestations

A. aphrophilus is a relatively rare cause of infection and disease in pediatric patients, with fewer than 50 cases reported in the literature.* Brain

abscesses and endocarditis are the pediatric infections reported most commonly.* Other reported sites of infection in children include the oropharynx,²⁶ the abdominal cavity,^{26,108} and various superficial soft tissue sites.^{160,233,234} Infections with *A. aphrophilus* do not appear to be associated with any distinctive clinical features compared with infection caused by other organisms at the same sites. However, *A. aphrophilus* infections frequently are associated with underlying conditions predisposing the host to infection, such as congenital heart disease, trauma, and immunosuppression.^{26,63,67,95,149,160,169,233}

Treatment

Antimicrobial susceptibility testing has not been well standardized for this organism, and disk-diffusion testing, in particular, has been found to be unreliable.^{26,94,160,213} Tube or agar dilution testing generally is considered to be the preferred testing method. Older reports found that *A. aphrophilus* was uniformly susceptible to several antibiotics, including chloramphenicol and the aminoglycosides.^{26,160,213} Susceptibility to penicillins has been variable. Even so, penicillin has been used successfully for treatment of susceptible organisms,^{26,82,160,226} at times in combination with aminoglycosides and other antimicrobials. Some reports document the usefulness of ampicillin or ceftriaxone for treatment of infection.^{22,146,157,181} Several different antibiotics probably can be used to treat *H. aphrophilus* infections successfully. The choice for treatment should be guided by appropriate in vitro susceptibility testing.

HAEMOPHILUS DUCREYI

Bacteriology

In 1889, Ducrey first identified *H. ducreyi* in purulent material recovered from genital ulcers of patients with soft chancre or chancroid.⁵⁴ Although unable to culture the organism in vitro, Ducrey was able to establish the specificity of the infectious agent by serial cutaneous inoculations.^{54,151} *H. ducreyi* originally was assigned to the *Haemophilus* genus because of its requirement for hemin (X-factor) and a guanosine plus cytosine content within the expected range for *Haemophilus* species.^{4,221} However, more recent studies, including genetic transformation and DNA hybridization analyses, suggest that *H. ducreyi* is not related to the true haemophili, such as *H. influenzae*, and possibly should be placed in a separate genus.^{4,221}

Since the 1990s, significant advances have been made in the understanding of bacterial components that contribute to disease pathogenesis. Two cytotoxins, a hemolysin, a diffusible cytolethal distending toxin,

*References 14, 22, 26, 61, 67, 98, 99, 108, 149, 167, 233, 234.

*References 22, 26, 32, 61, 67, 93, 99, 138, 149, 160, 167.

and two classes of serum resistance proteins have been identified; their respective genes have been cloned, and their potential contributions to disease pathogenesis have been investigated.* The lipooligosaccharide of *H. ducreyi* has been characterized in much greater detail, and relevant biosynthetic genes have been cloned and studied.^{3,18,65,145,212,222,240,130,172,204}

Genes encoding the major outer membrane proteins of the organism have been cloned and the corresponding proteins characterized,¹¹³ and a novel class of pili expressed by *H. ducreyi* has been identified.³⁷ *H. ducreyi* requires heme for growth, and several of the critical molecules required for heme acquisition and use have been identified.^{57,58,123,209,216} The knowledge gained from molecular characterization of these important bacterial components should enhance efforts to understand the pathogenesis of disease more clearly.

Epidemiology

Chancroid is a genital ulcerative disease that is found throughout the world. It is seen frequently in Africa, Asia, and Latin America, where it may be a more common cause of genital ulcer disease than syphilis.^{4,23–25,151,218,221} Although generally considered a relatively uncommon cause of illness in the United States, chancroid continues to be diagnosed, particularly among patients, including adolescents, who present with genital ulcer disease in large urban areas.^{28,87,92,147,148,195} Furthermore, data suggest that chancroid may be more common in the United States than suspected because it can be difficult to diagnose correctly using traditional clinical and laboratory means.^{53,152,221} Symptomatic disease among patients in the United States has been reported most commonly among nonwhite heterosexual male patients.^{28,68,87,151} However, symptomatic disease is not restricted to men, and female prostitutes have been implicated as important sources of infection in several of the outbreaks reported in the United States.^{28,87,151}

H. ducreyi has been the subject of renewed medical and scientific interest since the early 1980s. This interest followed from epidemiologic studies, primarily from Africa, demonstrating that the presence of genital ulcer disease (much of which was chancroid) was strongly associated with an increased risk of heterosexual transmission of human immunodeficiency virus (HIV) infection.^{2,9,104,116,117,152,171,229} Mechanisms proposed to explain this enhanced transmission included an increased shedding of HIV through the ulcers,^{116,221} an increased number of HIV-susceptible cells (e.g., CD4 T lymphocytes) in genital ulcers of a person being exposed to HIV,^{205,221} or an increased viral load in the blood and semen of persons coinfecting with HIV and *H. ducreyi*.⁵⁶

Pathogenesis

As noted earlier, significant progress has been since the 1990s in better understanding the pathogenesis of *H. ducreyi* infection.^{8,102,201,221} Several useful in vivo models of *H. ducreyi* infection have been developed. These include a temperature-dependent rabbit model of dermal infection,¹⁷³ a primate model of genital chancroid infection in adult pigtailed macaques,²¹⁹ a swine model of dermal infection,⁹⁶ and an experimental model of human infection.^{10,11,17,19,103,163,201,206} Several putative virulence factors have been identified, and their contributions to the pathogenesis of disease are being investigated using several in vitro and in vivo model systems. Some of the molecules and characteristics studied include bacterial lipooligosaccharide,^{20,39,130,204,242} pili,^{3,8,21,66,80,193,202,211,222} the cytolethal distending toxin,[†] an hemolysin,^{6,55,162,164,220,236,241} serum resistance proteins,^{1,44,75,125,126} lectin binding proteins,^{1,101,225,228} and the ability to adhere specifically to epithelial cells of genital origin.^{5,121} The contribution of these proposed virulence factors to the pathogenesis of natural infection in humans is still being defined.¹⁰² However, it is known that strains deficient in expression of several of these factors are attenuated in their ability to cause disease in the experimental model of human infection.^{9,33,70,73,101–103,182,203} Ongoing investigations of *H. ducreyi* undoubtedly will define the virulence mechanisms of the organism more clearly and should enhance efforts to develop protective vaccines.^{2,10,45,50,74,88,124}

Clinical Manifestations

The incubation period of chancroid usually is between 4 and 7 days. It rarely is less than 3 days or more than 10 days.^{7,151,185,186} Typically the first lesion noted is a small inflammatory papule surrounded by a zone of erythema. Within 2 or 3 days, a pustule forms that soon ruptures, leaving a sharply circumscribed ulcer with ragged undermined edges without induration.^{128,151,185} The base of the ulcer usually has a granular appearance and always is painful. In male patients, the most common sites of appearance of the ulcers are on the distal prepuce, on the mucosal surface of the prepuce on the frenulum, and in the coronal sulcus. In female patients, most lesions are at the entrance to the vagina.^{128,151,185} Painful, tender, inguinal adenopathy is present in up to 50% of patients and usually is unilateral. The involved lymph nodes rapidly may become fluctuant and rupture, with the formation of inguinal ulcers.^{151,185}

The combination of a painful ulcer and tender inguinal adenopathy is suggestive of chancroid and, when accompanied by suppurative inguinal adenopathy, is almost pathognomonic.²³⁷ However, a significant percentage of patients with *H. ducreyi* infection may have ulcers that can be confused with other genital ulcer diseases, such as herpes or syphilis.^{76,128,151,185} Furthermore, as many as 10% of patients with chancroid may be coinfecting with *Treponema pallidum* or herpes simplex virus.²³⁷ Thus it becomes mandatory to establish a definitive diagnosis by laboratory means if one is to be confident about the diagnosis.

Chancroid has also been described as a cause of chronic lower extremity skin ulcers in children in the South Pacific area^{139,150,224} and, more recently, in central Africa.⁷⁹ These are areas of the world in which yaws, caused by the spirochete *T. pallidum* subsp. *pertenue*, is endemic and where this organism was previously thought to be the primary cause of such ulcers. However, in a more recent study of children with chronic skin ulcers in one endemic region, the incidence of infection caused by *H. ducreyi* exceeded that of infection caused by *T. pallidum* subsp. *pertenue*. Furthermore, a small percentage of children actually had infection with both organisms simultaneously.^{150,184,200}

Diagnosis

As noted earlier, diagnosing chancroid on clinical grounds alone is difficult because the clinical presentation often is not classic, and many clinicians do not have much experience with the disease.^{221,237} Definitive diagnosis of chancroid requires isolation of the organism from a genital ulcer or from involved lymph nodes. However, the organism is fastidious and is difficult to isolate, even under the best of circumstances.¹⁵¹ To obtain specimens for culture, a swab should be used to obtain material from the purulent base of an ulcer, or a fluctuant inguinal lymph node should be aspirated directly. Gram stain of purulent material may reveal gram-negative rods in the characteristic “school-of-fish” pattern, but this appearance probably is more characteristic of in vitro propagated organisms.¹⁵¹ However, even with use of the selective media now recommended for isolation of *H. ducreyi*, it has been estimated that the sensitivity of culture is no higher than 80%.^{128,237}

Given the low sensitivity of culture, alternative non-culture-based diagnostic tests have been evaluated. Early studies examined the utility of diagnosing chancroid serologically with an enzyme-linked immunosorbent assay using either an outer membrane protein preparation or a lipooligosaccharide preparation of *H. ducreyi*.⁷ More recent studies have used slightly altered antigen preparations and serum preparation techniques meant to improve the sensitivity and specificity of the assay.⁴² Although these modifications did lead to improvement in the performance characteristics of the assay, the ability of the modified assay to aid in the diagnosis of acute infection remains limited because many patients do not develop a serum antibody response until several weeks after onset of infection.^{42,218} More recent work has focused on the use of recombinant proteins as test antigens for a serologic test.⁵⁹ This latter assay does appear to show promise for seroprevalence studies, but its utility in the diagnosis of acute infection has yet to be demonstrated. Another more recently described diagnostic test relies on detection of *H. ducreyi* with monoclonal antibodies directed against the hemoglobin receptor, but it has yet to undergo extensive field testing.¹⁶⁶

Nucleotide-based diagnostic methods also have been described.^{105,188,221} Perhaps most promising are the polymerase chain reaction–based

*References 1, 6, 44, 46, 75, 100, 125, 126, 161, 164, 225.

†References 48, 47, 72, 77, 83, 120, 131, 133, 174, 175, 208, 239.

techniques. These assays demonstrate high sensitivity and appear to identify some patients with chancroid, from whom bacterial cultures for *H. ducreyi* are negative.^{218,221,150} Multiplex polymerase chain reaction assays that can amplify and subsequently detect DNA from *H. ducreyi*, *T. pallidum*, and herpes simplex virus from genital ulcer specimens simultaneously are undergoing field trials and have shown early promise.^{136,159,221}

Even if chancroid is diagnosed definitively, it is recommended that patients also be tested for HIV at the time of diagnosis. In addition, up to 10% of patients with chancroid may be coinfecting with *T. pallidum* or herpes simplex virus.²³⁷ Appropriate testing for these other pathogens should be strongly considered when a patient presents with any form of genital ulcer disease.

Treatment and Prevention

Successful antimicrobial treatment of genital ulcers caused by *H. ducreyi* cures the infection, resolves clinical symptoms, and prevents transmission to others. However, in cases of extensive ulcerative disease, scarring may result, despite successful antimicrobial therapy.²³⁷ The Centers for Disease Control and Prevention currently recommend one of four antibiotic regimens for treatment of chancroid in adolescents and adults.^{128,194,237} These regimens are: (1) azithromycin, 1 g orally in a single dose, (2) ceftriaxone, 250 mg intramuscularly in a single dose, (3) ciprofloxacin, 500 mg orally twice a day for 3 days, or (4) erythromycin base, 500 mg orally three times a day for 7 days.^{194,237} All four regimens are generally effective for treatment of chancroid among patients without HIV infection.¹⁹⁴ A successful response to therapy usually is apparent within 48 to 72 hours, as shown by decreased ulcer tenderness and pain.^{185,194,237} Complete healing of ulcers may take up to 28 days but often is achieved in 7 to 14 days.¹⁸⁵ Healing of fluctuant adenopathy is slower than that of the ulcers and may require needle aspiration through adjacent intact skin or incision and drainage to achieve a successful response to therapy.^{62,194}

Patients with HIV infection must be monitored closely because they may require longer courses of antimicrobial agents than the standard regimens just outlined.^{194,237} Treatment failures have been noted with several of these regimens,^{31,194,223} and there is some suggestion that persons who are most immunosuppressed are at the greatest risk for failure of standard regimens.²²³ Some experts recommend using the erythromycin 7-day regimen for treating all HIV-infected patients because of good experience with this regimen in the HIV-infected population and limited successful experience with the alternative regimens.¹⁹⁴

Identifying all sexual contacts of infected persons is critical to prevent further spread of *H. ducreyi* disease. The Centers for Disease Control and Prevention recommend that all persons who have had sexual contact with a patient with proven *H. ducreyi* infection within the 10 days before onset of the patient's symptoms be examined and treated.²³⁷ Contacts should be examined and treated even in the absence of symptoms.

In the longer term, alternative strategies for control of chancroid should be examined. If feasible, vaccination for prevention of *H. ducreyi* infection would be a worthy goal. Data generated in animal models of infection are somewhat encouraging.^{2,50,88,191} Protective immunity to both homologous and heterologous challenge has been reported after immunization of rabbits with cell-surface extracts of *H. ducreyi*.⁸⁸ In other work, a purified pilus preparation also was reported to induce immunity in that same model.⁵⁰ More recently, immunization with the hemoglobin receptor protein was reported to protect against infection in the swine model of chancroid.^{2,74,124} These data suggest that prevention of chancroid by vaccination may be an achievable goal. However, data from the experimental human model of infection suggest that development of a protective vaccine for human use may not be a straightforward process.^{10,103}

HAEMOPHILUS INFLUENZAE BIOGROUP AEGYPTIUS (HAEMOPHILUS AEGYPTIUS)

Bacteriology

H. influenzae biogroup *aegyptius* (*H. aegyptius*) was described originally by Koch¹¹⁴ in 1883 in Egyptian patients with conjunctivitis. A more

detailed description of the organism and the clinical characteristics of disease followed 3 years later in the work of Weeks.²³¹ The Koch-Weeks bacillus has continued to be an important cause of conjunctivitis since these initial reports. Because of several reportedly unique characteristics,¹⁴¹ the Koch-Weeks bacillus originally was designated as a unique species of the *Haemophilus* genus (*H. aegyptius*) distinct from *H. influenzae*. However, more recent phenotypic and phylogenetic studies, including DNA relatedness analyses, have raised questions about the validity of this separation.^{36,214} The organism is known currently as *H. influenzae* biogroup *aegyptius*, although debate continues in the literature about the appropriateness of this designation.¹³²

This organism became the subject of intense scientific study in the 1980s as a result of its association with a newly described fulminant and often fatal disease called Brazilian purpuric fever.^{34,35} *H. influenzae* biogroup *aegyptius* was isolated from 9 blood cultures and 1 hemorrhagic cerebrospinal fluid culture collected from 10 clinically ill children in Serrana, São Paulo State, Brazil.³⁵ The *H. influenzae* biogroup *aegyptius* strains causing Brazilian purpuric fever were initially believed to be members of a single virulent clone.^{36,214} This clone was characterized by the presence of several unique features, including a 24-MDa plasmid with a characteristic restriction endonuclease pattern,³⁶ a unique multilocus electrophoretic enzyme typing pattern,¹⁵⁶ one of two rRNA gene restriction fragment length polymorphisms,^{36,51} a single sodium dodecyl sulfate–polyacrylamide gel electrophoresis profile for whole-cell lysates,³⁶ specific reactivity with monoclonal antibodies recognizing epitopes unique to Brazilian purpuric fever strains,^{127,214} agglutination with antisera specific for the Brazilian purpuric fever clone,³⁶ and conservation of certain major outer membrane proteins.¹⁷⁹ Although most Brazilian purpuric fever–associated strains of *H. influenzae* biogroup *aegyptius* appeared to be members of a unique clone, a few Brazilian purpuric fever–associated strains were identified that lacked some of the defining characteristics.^{214,217} Furthermore, two cases of Brazilian purpuric fever reported from Australia were associated with strains clearly distinct from the Brazilian purpuric fever clone.^{132,214} An excellent review of the epidemiologic, clinical, and laboratory aspects of the disease and its investigation has been published, and the reader is referred to that work for additional information.⁹¹

Epidemiology

In the United States, *H. influenzae* biogroup *aegyptius* has remained an important cause of conjunctivitis, with disease most commonly reported from the southern states.⁹⁰ The United States experienced only one reported case of possible Brazilian purpuric fever.²²⁷ In Brazil, the epidemiology of Brazilian purpuric fever became more clearly defined with time.^{90,91} The median age of patients with Brazilian purpuric fever was 2 to 3 years, with an overall age range of 3 months to 10 years.^{34,35} Brazilian purpuric fever appeared to occur with the onset of warmer temperatures and was less likely during the Brazilian winter.⁹⁰ Furthermore, it appeared to be more common in small agricultural towns than in larger cities.^{34,35,90} Case-control studies attempting to identify risk factors for development of disease identified a history of preceding conjunctivitis as being associated strongly with the development of Brazilian purpuric fever.^{34,35,90} (although many of the control subjects also gave a history of conjunctivitis) and suggested that day care center attendance was an additional risk factor.³⁵ There have been no additional reported cases of Brazilian purpuric fever since the early 1990s. The reasons for the apparent disappearance of the disease remain unclear.⁹¹

Pathogenesis

Efforts to identify unique virulence factors of *H. influenzae* biogroup *aegyptius* responsible for the fulminant nature of Brazilian purpuric fever have been ongoing since the initial descriptions of the illness. Progress to date has been limited,^{40,91} but several more recent genome-based studies demonstrated clear differences between *H. influenzae* biogroup *aegyptius* prototype strains and other *H. influenzae* strains.^{129,144,199} Brazilian purpuric fever clone strains express certain novel or unique surface molecules or secreted proteins that theoretically could result in enhanced virulence.^{36,40,127,132,190,235} Distinctive lipooligosaccharide phenotypes,^{40,190} immunoglobulin A proteases,^{40,132,143} pili,^{18,177,178,235}

secreted proteins,²³⁵ and adhesins^{196,210} have been reported for Brazilian purpuric fever strains. However, none has been shown to have a specific dominant role in bacterial virulence. One study suggested that the risk of developing Brazilian purpuric fever correlated with the lack of serum bactericidal activity against the Brazilian purpuric fever clone, but this observation needs further confirmation.¹⁸⁹ In more recent work using a comparative genomic approach, investigators identified differences in known autotransporter adhesins as well as adhesins unique to the Brazilian purpuric fever clone that may play a role in pathogenesis.²¹⁰

Both in vitro and in vivo models were developed for further investigating the pathogenesis of Brazilian purpuric fever.^{176,190,232} In these model systems, Brazilian purpuric fever–associated strains demonstrated increased virulence compared with control strains not associated with Brazilian purpuric fever, but again, the specific molecular correlates of this increased pathogenicity have yet to be identified clearly.^{176,190}

Clinical Manifestations

The clinical presentation of Brazilian purpuric fever is distinctive and dramatic.^{34,35,90,91} The syndrome initially manifests as purulent conjunctivitis without distinguishing characteristics. Symptoms of Brazilian purpuric fever typically appear 3 to 15 days later, after the conjunctivitis has resolved. Affected children experience the acute onset of fever, which may be associated with vomiting and abdominal pain. Death frequently ensues within 48 hours after the development of disseminated purpura, vascular collapse, and hypotensive shock. The precise pathophysiologic mechanisms responsible for progression from conjunctivitis caused by the Brazilian purpuric fever clone to full-blown Brazilian purpuric fever are unknown. The overall case-fatality rate since Brazilian purpuric fever first was recognized is estimated to be 70%.⁹⁰ Children may develop conjunctivitis with the Brazilian purpuric fever clone and, after recovery from the conjunctivitis, have no further problems.⁹⁰ The risk factors that predispose only some children to develop Brazilian purpuric fever are not well understood.

Treatment

Data from the limited number of Brazilian purpuric fever cases studied suggest that early antimicrobial therapy may improve survival.³⁵ One suggested regimen is high-dose ampicillin and chloramphenicol. The small number of patients treated to date does not permit a comparison of the efficacy of different antibiotic regimens.³⁵ Most of the patients who developed Brazilian purpuric fever in the Brazilian studies were treated with topical antimicrobials for conjunctivitis, yet they still developed systemic disease.³⁵ This finding suggests that local topical therapy is ineffective in eradicating the organism from the host. One study examined the relative efficacy of oral rifampin and topical chloramphenicol in eradicating conjunctival carriage of the Brazilian purpuric fever clone.¹⁶⁸ Although the number of patients who actually carried the Brazilian purpuric fever clone was small, rifampin was shown to be significantly better in eradicating carriage of the Brazilian purpuric fever clone than was topical chloramphenicol.

HAEMOPHILUS PARAINFLUENZAE

Bacteriology

H. parainfluenzae was identified first as a species distinct from *H. influenzae* by Rivers in 1922.¹⁸³ Both organisms are fastidious, gram-negative coccobacilli, but with in vitro culture, *H. parainfluenzae* can be propagated on nutrient agar plates with supplemental factor V alone (hence the “para” designation), rather than with both factor X and factor V, which are required by *H. influenzae* isolates (see Table 134.1). Testing for hemolysis on blood-containing media differentiates *H. parainfluenzae* from hemolysis-producing species, such as *H. haemolyticus* and *H. parahaemolyticus*.^{112,122} Recovery of *H. parainfluenzae* organisms from blood cultures is enhanced by routine subculturing of all specimens. The organisms tend to grow as small colonies along the side walls of the blood bottles or in the red blood cell mass, thus leaving the broth clear. Routine subculturing to supplemented chocolate agar and incubation with supplemental carbon dioxide should allow recovery of any *H. parainfluenzae* organisms that are present.^{43,86}

Epidemiology and Pathogenesis

H. parainfluenzae is found commonly in the oropharyngeal flora of normal children.^{85,119,135} The organism can be recovered from oropharyngeal cultures of one-fourth or more of healthy children. Of children who develop serious invasive disease caused by *H. parainfluenzae*, more than one-half give histories of identifiable preceding illnesses, such as upper respiratory tract infection, otitis media, and dental infections,^{15,27,85,97} a finding suggesting that local inflammation in the upper respiratory tract may predispose to transient bacteremia with this organism, which allows for seeding of other sites, such as the meninges and the heart valves. No specific virulence factors of the organism have been identified to date.

Clinical Manifestations

H. parainfluenzae remains an uncommon cause of infection in pediatric patients, but an increasing number of cases have been reported since the 1970s.²⁷ The most commonly reported infection is meningitis.* The clinical courses of the patients described with *H. parainfluenzae* meningitis are not remarkably different from those typical of acute bacterial meningitis caused by other organisms. However, the average age of affected children is 2.2 years,²⁷ an age significantly greater than that of the typical pediatric patient with bacterial meningitis.

The next most commonly reported infection is endocarditis.^{27,29,30,38,60,64,78,134,135,197} *H. parainfluenzae* endocarditis has several unique features. The reported cases of pediatric endocarditis usually occur in adolescents and involve girls more commonly than boys.²⁷ The clinical presentation often is subacute and frequently is not associated with localizing signs on physical examination (i.e., pathologic murmurs), at least initially.^{43,134,135} Another unique feature of *H. parainfluenzae* endocarditis is the high incidence of major arterial occlusion secondary to release of large emboli from the heart.^{27,43,78,134,207} This high incidence of embolization is thought to reflect the particularly friable nature of the vegetations.^{27,78} Another characteristic feature noted by several investigators is the relatively slow and variable response to antimicrobial therapy of endocarditis caused by this organism.^{27,43,134,135}

Other *H. parainfluenzae* infections reported in pediatric patients include brain abscesses,^{85,137} septic arthritis,²⁷ urinary tract infection,^{13,27,89} peritonitis,¹⁴⁰ and sepsis in neonates.^{41,81,110,180}

Treatment

H. parainfluenzae usually is susceptible in vitro to multiple antibiotics, including chloramphenicol, aminoglycosides, trimethoprim-sulfamethoxazole, and third-generation cephalosporins.^{27,43,106,135} Although most isolates in the past were susceptible to penicillins, more recent studies have documented an increasing incidence of β -lactamase-producing strains resistant to penicillin and ampicillin.^{27,192} For β -lactamase-negative penicillin-susceptible organisms, administration of ampicillin with an aminoglycoside has been recommended for serious *H. parainfluenzae* infections.^{43,154} Individual case reports document successful treatment with a variety of other antimicrobials, including ampicillin alone, cephalosporins, chloramphenicol, and trimethoprim-sulfamethoxazole.^{38,43,107,135} At present, pending results of susceptibility testing, it would be reasonable to initiate therapy for serious *H. parainfluenzae* infections with a third-generation cephalosporin, perhaps in combination with an aminoglycoside.

Helicobacter pylori

Aldo Maspons • Mark A. Gilger

The discovery of *Helicobacter pylori* in 1983 as the bacterial cause of peptic ulcer disease revolutionized the understanding, diagnosis, and treatment of acid peptic disease.¹¹⁵ *H. pylori* appears to infect approximately 50% of the world's population, thus rendering it one of the most common bacterial infections in humans.^{15,83} An understanding of *H. pylori* is important to pediatricians because this infection usually is acquired in childhood.⁶¹ This chapter details current consensus and understanding of this important pathogen.

BACKGROUND

The presence of bacteria in the gastric mucosa has been known for more than 100 years. In 1874, Böttcher¹ observed bacteria in the human stomach. Bizzozero⁴⁷ described spirochetes in the stomach of dogs in 1893. In 1938, Doenges⁶⁸ explored the issue of gastric spirochetes and their clinical relevance. He reported a 43% prevalence of spiral organisms in the human stomach in an autopsy review of 242 patients without known gastrointestinal disease. Specimen autolysis, however, rendered interpretation of the pathologic significance of the gastric spirochetes impossible. Freedberg and Barron⁴⁶ verified the findings of Doenges in 1940, when they identified spirochetes in the stomachs of 37% of patients who had undergone partial gastric resection for carcinoma or ulcer disease. Work on the clinical significance of gastric spiral bacteria continued until a report by Palmer¹⁰⁷ was published in 1954. In an attempt to confirm the findings of spirochetes in the gastric mucosa, Palmer performed an exhaustive review of gastric fundus biopsies from 1000 adult patients, 80% of whom were being evaluated for upper gastrointestinal complaints and 20% of whom were healthy control volunteers. Palmer noted, "None of the 1180 specimens was found to contain spirochetes or any structure which could reasonably be considered to be of spirochetal nature."¹⁰⁷ He concluded that spirochetes are not part of the human gastric mucosa in health or illness. Palmer, a prominent researcher in gastritis, inadvertently may have curtailed further research into the role of gastric spiral bacteria.

In 1975, Steer,¹²⁶ using electron microscopy, noted curved bacteria in stomach biopsy specimens from patients with gastric ulcers. A few years later, Warren, an Australian pathologist, noted the appearance of spiral bacteria overlying inflamed gastric mucosa. He and Marshall began a series of culture experiments using *Campylobacter*-specific methods because the organism looked like a *Campylobacter*. In an attempt to fulfill the remainder of Koch's postulates, Marshall and associates⁹³ and Morris and Nicholson⁹³ independently ingested pure cultures of *H. pylori*, and symptomatic acute gastritis developed in both groups. The organism subsequently was recovered from the gastric mucosa by endoscopy and successfully cultured, thus completing Koch's postulates.

MICROBIOLOGY AND PATHOPHYSIOLOGY

H. pylori initially was named *Campylobacter pyloridis* because of its resemblance to *Campylobacter* spp.,⁷³ and the name was later changed to *Campylobacter pylori*. However, it became clear that the bacterium did not belong to any known genus. An entirely new genus, *Helicobacter*, was created, with *helico* describing the spiral shape and *pylori* denoting its typical location. *H. pylori* is a spiral-shaped, gram-negative bacterium with four to seven unipolar sheathed flagella (Fig. 135.1).^{11,105} It is 0.5 μm wide and 3 to 5 μm long and has a smooth surface.^{3,88} It generally is S-shaped in vivo but can take on many forms, from U-shaped to cocci to rodlike.⁹⁵

H. pylori inhabits a unique ecologic niche—the submucosa of gastric epithelium. Several attributes, including adherence, shape, microaerophilism, urease production, and motility, allow adaptation to the acidic gastric environment. *H. pylori* overlies the intercellular tight junctions of epithelial cells, beneath the mucous layer. Specific adhesion molecules appear to be tropic to gastric mucus-producing cells.⁹⁵ This adherence allows the organism to maintain colonization despite the rapid gastric cell turnover.⁷⁸ The spiral shape may allow the organism to corkscrew through the gastric mucus (see Fig. 135.1). This spiral movement has been demonstrated in vitro with methylcellulose solutions.⁷⁸ *H. pylori*

is microaerophilic and grows slowly in culture media (Table 135.1).^{12,106} Translucent colonies of 1 mm grow after 5 to 7 days on blood-supplemented or serum-supplemented media with a low concentration of oxygen and carbon dioxide at a temperature of 37°C (98.6°F), which promotes optimal growth. This microaerophilism is well suited to the low oxygen levels of the gastric submucosa.⁷⁷ *H. pylori* is the most potent urease producer of any known microbe; researchers have estimated that as much as 10% of its total protein production is urease, and the organism appears to surround itself in a cloud of ammonia.⁹ The urea is converted to ammonium and bicarbonate.^{11,53} Little evidence supports the notion that the ammonium produced is cytotoxic to gastric epithelium.⁶² The bicarbonate creates an alkaline environment in the gastric

FIG. 135.1 Electron microscopy of *Helicobacter pylori* demonstrating the multipolar flagella and the typical spiral shape.

TABLE 135.1 Examples of Gastric Biopsy Cultures

Culture Media	Incubation Period (Days)	Conditions
Brucella chocolate agar with 7% sheep blood ⁸⁵	7	Microaerobic
Preserved in brain-heart infusion broth with 5% glycerin inoculated onto Columbia agar plates with 5% fresh defibrinated sheep blood ¹²⁸	3	Microaerophilic
Columbia III agar with 5% sheep blood ²³	10–14	Microaerophilic

submucosa. *H. pylori* produces several other enzymes, including mucinase,¹²⁴ lipase,⁶⁹ catalase,⁸⁴ hemolysin, and cytopathic toxin.⁸² The multiple, unipolar flagella (see Fig. 135.1) provide motility that may enable the organism to escape the acid lumen of the stomach and evade host immune responses.^{77,78}

H. pylori may be more akin to normal gastrointestinal flora because the bacterium and the host can coexist for decades without apparent problems.⁵⁴ *H. pylori* infection produces inflammation, although in most cases the host is asymptomatic.¹⁴ The inflammatory response is characterized by infiltration of polymorphonuclear leukocytes, monocytes, lymphocytes, and plasma cells into the lamina propria (Fig. 135.2).⁸⁴ A significant immune response, including the production of antibodies, is generated by the host, but it does not clear the organism in most cases.⁸² *H. pylori* produces a chronic infection that persists for decades, possibly for life.⁸⁴ This lifelong colonization is accomplished by the same features that allow survival in the gastric mucosa, namely, high urease production, flagellar motility, spiral shape, microaerophilism, and adherence.⁸⁴

Numerous potential virulence factors, such as urease, catalase, cytotoxin, and lipopolysaccharide, have been identified, although whether any of these substances actually contribute to symptomatic disease is unknown. The urease of *H. pylori* is a potent antigen that induces elevations in antiurease immunoglobulin (Ig) G and IgA.⁸⁴ Interestingly, the ammonia produced by the urease does not appear to have a significant role in pathogenesis.⁵⁶ Catalase, another *H. pylori* enzyme, prevents the formation of oxygen metabolites from hydrogen peroxide in neutrophils,³³ a feature that may provide an ability to evade host destruction. A vacuolating cytotoxin has been identified in many *H. pylori* strains,³³ although whether it is more common in patients with symptomatic disease is unclear. *H. pylori* has a peculiar lipopolysaccharide outer membrane. Unlike most gram-negative bacteria, its lipopolysaccharide coat is a significantly less potent inducer of the host complement cascade, some 1000-fold less potent than that of the Enterobacteriaceae.⁸⁴ This low biologic activity of the outer membrane of *H. pylori* may be another adaptive mechanism allowing gastric colonization.¹³

The most pathogenic strain of *H. pylori* contains a cytotoxin-associated gene pathogenicity island (Cag PAI).^{118,119} The Cag PAI encodes a type IV secretion system with a pilus that directly injects Cag A into the host's cytoplasm. Cag A affects gastric epithelial functions that include cell proliferation and suppression of apoptosis, as well as affecting intercellular junctions.⁷ Cag A-positive strains are considered more virulent because of Cag A involvement in the intestinal cell transdifferentiation of gastric epithelial cells, a precursor to carcinogenesis.^{101,102}

EPIDEMIOLOGY

H. pylori infection is one of the most common bacterial infections in humans, with an estimated 1 billion people in the world infected.^{15,73} It is estimated that in developing countries more than 80% of the population is infected with *H. pylori*, whereas in industrialized countries

FIG. 135.2 (A) Chronic active gastritis. Corpus mucosa displays a large lymphoid infiltrate (magnification $\times 100$; hematoxylin and eosin stain). (B) *Helicobacter pylori* are abundant at the surface and line the mucous glands of the gastric pit (magnification $\times 640$; silver stain). (Courtesy Dr. Milton J. Finegold, Baylor College of Medicine, Texas Children's Hospital, Houston, TX.)

FIG. 135.3 Seroepidemiology of *Helicobacter pylori* infection demonstrating the difference in disease prevalence between developing and developed countries. (Data from Graham DY, Adam E, Reddy GT, et al. Seroepidemiology of *Helicobacter pylori* infection in India: comparison of developing and developed countries. *Dig Dis Sci*. 1991;36:1084–1088.)

the infection rate remains lower than 40% (Fig. 135.3).¹⁰⁹ Transmission appears to be from person to person.^{79,130} Transmission through the fecal-oral route is the primary mode of infection. The presence of pets may be a risk factor for *H. pylori* infection, given that the bacterium has been isolated from domestic animals.^{16,28} Interestingly, breastfeeding appears to increase the risk for acquiring *H. pylori* infection, possibly secondary to close contact with infected mothers, and breast milk does not protect against infection.^{116,138} *H. pylori* usually is acquired in childhood,²⁴ and humans appear to be natural reservoirs for infection.⁵⁵ Environmental sources of *H. pylori* infection, such as municipal water sources, have been confirmed in Peru and Mexico.^{87,96}

Children are important factors in the transmission of *H. pylori* infection, which clusters within families with children.^{31,91,103} Family clustering emphasizes the role of crowding and personal hygiene in the person-to-person spread of infection. The prevalence of infection increases with age. In the United States, for example, only approximately 20% of persons younger than 30 years of age are infected, in contrast to 50% of those older than 60 years.⁹⁴ Infection in young children is rare in the United States and developed nations. The phenomenon of increasing prevalence with age most likely reflects a cohort effect; that is, the high prevalence in older persons simply reflects a higher childhood infection rate.⁸⁴ This cohort effect may be explained best by a lower standard of living of older persons during childhood. Socioeconomic status varies inversely with the prevalence of infection, with low-income persons having the highest rates of infection.⁴¹ Conversely, Ozen and associates¹⁰⁶ found that low household population and a history of antibiotic use during the previous 6 months served as protective factors against infection. A higher prevalence of infection exists in developing countries than in developed countries (see Fig. 135.3).⁹⁵ and the prevalence of infection varies greatly around the world. In Nigeria, for example, 58% of children younger than 1 year of age and 91% of children older than 10 years of age were infected.⁶⁴ Such differences have been attributed

to socioeconomic factors, hygiene, and the number of household occupants.¹²³ *H. pylori* is more prevalent in blacks and Hispanics than in whites in the United States.¹²⁵

The rate of *H. pylori* reinfection in the pediatric population ranges from 2.4% to approximately 20% per year.^{70,116} Magista and colleagues⁹⁰ demonstrated that the difference in reinfection rate depends primarily on the socioeconomic status of the family and the local prevalence of *H. pylori*. These investigators and others^{39,40} also noted that living in an area with a high prevalence of *H. pylori* resulted in a fourfold higher risk of reinfection.

CLINICAL MANIFESTATIONS

Gastritis develops in most *H. pylori*-infected patients, but complications associated with infection develop in only a few.¹⁵ This finding is especially true in children, in whom peptic ulcer is considerably less common than in adults. To confound matters, children have no specific symptoms of *H. pylori* infection.¹¹⁵ Symptoms such as epigastric pain, nighttime awakening with abdominal pain, hematemesis, and recurrent vomiting are suggestive but in no way predictive of infection.⁷² Because these clinical symptoms are typical of peptic ulcer disease, testing for *H. pylori* infection alone has no relevance but rather should be done to determine the presence of an underlying condition.⁷⁵ Such symptoms possibly are present only if *H. pylori* infection is found with a duodenal ulcer. Furthermore, the presence of *H. pylori* infection alone in both adults and children usually is asymptomatic.^{27,59}

Presumed *H. pylori* infection should not be empirically treated, given the low likelihood of resolution of abdominal pain.⁷⁶ If the child has active upper gastrointestinal complaints, then *H. pylori* infection should be considered and diagnosed accordingly. Other clinical manifestations of *H. pylori* include protein-losing enteropathy and iron deficiency anemia.^{20,22} Indeed, successful treatment of *H. pylori* infection improves iron stores.¹⁸ Eradication of the bacteria should always be the goal, given that the infection is the most consistent risk factor for gastric cancer.⁹²

DIAGNOSIS

The gold standard for diagnosis of *H. pylori* infection is culture of the organism from gastric biopsy samples or histologic review. Upper gastrointestinal endoscopy and other invasive means are necessary to obtain such biopsy specimens. In children, upper endoscopy can be quite helpful in that it often reveals a distinct nodularity at the antrum (Fig. 135.4), but findings also may appear normal. This nodularity is found in two-thirds of infected children but only rarely in adults.¹⁷ Histologically, prominent lymphoid follicles are seen. Routine staining with hematoxylin and eosin may be adequate but must be performed properly to see the bacteria clearly. Alternative staining techniques, such as acridine orange, silver stains, and the “triple” stain, improve visualization.^{49,89} The triple, or Genta, stain (Steiner, hematoxylin and eosin, Alcian blue) may offer some distinct advantages because it is significantly more sensitive than hematoxylin and eosin staining and is particularly useful for the detection of small numbers of bacteria, as often is the case in children (see Fig. 135.2). Although culture and histologic examination require endoscopy, culture may be important, especially when considering the increase in antibiotic resistance worldwide.^{6,26} In cases of recurrent *H. pylori* infection in which antibiotic resistance is suspected, culture allows *in vitro* antibiotic susceptibilities to be determined.

Noninvasive methods for detection of *H. pylori* infection are detailed in Table 135.2 and include serology, varying methods for detection of urease production, detection of salivary antibody, stool culture, stool antigen, polymerase chain reaction (PCR), and urine ammonia production. The carbon-13 (¹³C)-urea breath test is considered the best available noninvasive diagnostic test in children.^{15,36} In 2012, it was approved by the US Food and Drug Administration to detect and monitor *H. pylori* infection in pediatric patients 3 to 17 years of age. Serology, conversely, is not useful. Measurement of *H. pylori* stool antigen can be performed by either a polyclonal or monoclonal antibody technique.^{35,71} This test detects the presence of antigen, thus providing evidence of active infection

for both primary diagnosis or proof of cure. It appears to be as accurate as the urea breath test.

H. pylori infection induces a vigorous neutrophilic and lymphocytic (T-cell and B-cell) response that fails to clear the infection. The humoral immune response produces antibodies that can be detected in gastric secretions, as well as systemically. Some *H. pylori* antigens have been determined with the use of bacterial cell wall sonicates, urease, or

membrane extracts as the capture antigen. Some commercial assays have been found to have inappropriate positive and negative cutoff values for use in children.²⁵ Care must be taken to ensure that the serologic tests performed have been verified for use in children. Although detection of IgA, polymeric IgA, and IgM antibodies against haptoglobin can be performed, such detection is not reproducible and thus has no clinical value. Serologic diagnosis, although simple and widely available, does not indicate symptomatic disease.

H. pylori is a vigorous producer of urease. This characteristic has been used to create a variety of tests to detect the presence of urease. The urea breath test uses a labeled carbon of urea, either radioactive ^{14}C ¹⁰ or a nonradioactive, stable isotope ^{13}C .⁵⁷ Patients fast for 4 to 8 hours and then drink the labeled carbon accompanied by a meal to delay gastric emptying; then the amount of labeled carbon dioxide in the breath is measured. Only patients with gastric *H. pylori* present (and thus gastric urease activity to degrade the labeled urea) are identified. Urea breath testing is useful for both initial diagnosis and determination of successful treatment because the results rapidly return to normal after eradication of the bacterium. The radioactive ^{14}C method does not deserve consideration for use in children. The stable isotope ^{13}C method currently is the simplest and most accurate noninvasive test available for detection of *H. pylori* infection. Its usefulness remains limited, however, because of the need for specialized equipment for analysis.

The urease production of *H. pylori* can be measured directly in gastric biopsy specimens with a variety of commercial assays.³ A portion of the gastric biopsy specimen is placed into a urea medium, and hydrolysis of urea leads to a color change in the medium from tan to pink. False-negative results have been noted in children because of the low numbers of organisms.³² Such testing is useful for establishing a

FIG. 135.4 Endoscopic view of the gastric antrum and body demonstrating marked nodularity of the gastric surface.

TABLE 135.2 Summary of Methods for Detecting *Helicobacter Pylori*

Method	Sensitivity (%)	Specificity (%)	Advantages	Disadvantages
Invasive				
Histology	93–99	95–99	Widely available; detection best with special stains; can evaluate underlying mucosal damage; gold standard	Expensive; at least two biopsies required; observer error; recent antibiotics or proton pump inhibitor use can lead to false-negative results
Culture of biopsy specimens	77–92	100	In vitro antibiotic susceptibility can be determined	Expensive; organism requires special transfer and culture technique; requires up to 1 week for results; recent antibiotics or proton pump inhibitor use can lead to false-negative results
Rapid urease test (CLO test, hpFast, PyloriTek)	89–98	93–98	Rapid results; easy to perform; less expensive than other invasive techniques	Formalin, simethicone, local anesthetic spray, recent antibiotics, bismuth, or proton pump inhibitor use can lead to false-negative results; poor technique or handling affects results
Noninvasive				
Urea breath test (^{13}C , ^{14}C)	90–100	89–100	Inexpensive; represents entire mucosa (not subject to biopsy sampling bias)	Antibiotics or proton pump inhibitor use can lead to false-negative results; presence of ulcer disease not determined; can be difficult to collect in children <2 y old
Serology (ELISA; HM-CAP, Pylori.STAT)	44–99	89–95	Widely available; inexpensive	Not useful after treatment
Rapid serology (FlexSure, QuickVue)	92–93%	75–88%	In office diagnostic kit, widely available	Not useful after treatment
Stool antigen testing	85–94	97.7	Inexpensive; more accurate than serology; may become the test of choice in children	Stool must be collected
Saliva	71–93	82–92	Easy to collect; inexpensive;	Low sensitivity, especially in children <2 y old
Urine (anti- <i>H. pylori</i> IgG antibodies in urine)	90	100	rapid results; easy to perform; does not require large bacterial load	Length of time needed to prove eradication not known

CLO, *Campylobacter*-like organism; ELISA, enzyme-linked immunosorbent assay; HM-CAP, high-molecular-weight, cell-associated protein; IgG, immunoglobulin G. Data from references 51, 104, and 117.

rapid diagnosis during endoscopy but requires gastric biopsy. Urease activity also can be detected by measurement of another nonradioactive, stable isotope, ammonium, in the urine after oral ingestion.¹⁴⁰ This noninvasive test has not proved to be accurate. *H. pylori* has been identified in saliva and dental plaque by culture⁷⁴ and PCR.²¹ Other investigators have identified salivary antibody to *H. pylori* with an indirect immunofluorescence assay.⁶⁵ The saliva test is not accurate in young children and cannot be recommended.⁵¹ Viable *H. pylori* organisms have been cultured from feces in Gambian children.

Proton pump inhibitors (PPIs) should be stopped, ideally, at least 2 weeks before testing because PPI use can lead to a decrease in the bacterial load and raise the possibility of a false-negative result. Histamine H₂ blockers can do the same, but to a lesser extent. After 2 weeks, the bacterial load begins to increase.

TREATMENT

The first-line therapy for *H. pylori* infection in children has long been a twice-daily, three-drug regimen that includes amoxicillin, clarithromycin, and a PPI given for 14 days.⁵⁰ Table 135.3 presents a variety of suggested regimens for the treatment of *H. pylori* infection in children.

Confirmation of successful treatment has been defined as the absence of detectable organisms by tissue biopsy, urea breath test, or stool antigen testing at least 1 month after completion of treatment.⁵⁰ Because tissue biopsy is invasive, urea breath testing or stool antigen detection is helpful for determination of successful treatment. Serologic tests are not useful for detection of cure because of the prolonged elevation of titers, which remain elevated for 6 months to 1 year or longer after treatment. Moreover, not all serologic tests are equivalent.

A growing body of evidence indicates that acquisition of *H. pylori* infection in childhood is a significant risk factor for the development

of gastric cancer such as adenocarcinoma (Fig. 135.5).^{66,133} An estimated two- to sixfold increased risk for the development of gastric cancer exists among *H. pylori*-infected patients.^{30,132} Patients in whom gastric cancer develops appear already to have atrophic gastritis or metaplasia at baseline.^{43,139} This finding argues for treatment of *H. pylori* infection in childhood, before the onset of atrophic gastritis. The location of the infection within the stomach may influence the outcome. For example, antral-predominant infection more commonly leads to increased acid secretion, which results in duodenal peptic ulcers and a low risk for gastric cancer. In contrast, fundus-predominant infection leads to decreased acid secretion, which results in atrophic gastritis and a higher risk for gastric cancer.⁸¹ Treatment of gastric lymphoma with antibiotics directed at *H. pylori* results in regression of the tumor.⁵

Some researchers argue that the risk for developing either lymphoma or adenocarcinoma provides cause for the treatment of all children infected with *H. pylori*. Because the risk for development of cancer cannot be predicted accurately and because most children with *H. pylori* infection have no clinical symptoms, no current rationale exists for treating all children infected with *H. pylori*.

In children, the most common anti-*Helicobacter* therapy is legacy triple therapy, which includes amoxicillin, clarithromycin, and a PPI (see Table 135.3). Resistance to clarithromycin, however, has led to a decline in efficacy from 34% to 66% and eradication rates of less than 80%.^{42,134} Clarithromycin resistance varies, and success depends on resistance rates. When resistance is less than 10%, then clarithromycin-containing regimens are recommended as the first-line treatment; efficacy of the regimen can be increased by 8% to 12% if a double-dose PPI is given, and extending the therapy to 14 days can increase success by 5%.⁹² Eradication rates greater than 90% were demonstrated when *H. pylori* susceptibility testing was performed in children.^{4,127} Antimicrobial evasion to clarithromycin, for example, has been attributed to three

TABLE 135.3 Suggested Treatment Regimens for *Helicobacter Pylori* Infection in Children

Medications	Dosage	Duration (Days)
Triple Therapy		
Amoxicillin ^a	50 mg/kg/day twice daily (max, 1 g twice daily)	7–14
Clarithromycin	15 mg/kg/day twice daily (max, 50 mg)	7–14
Proton pump inhibitor ^b (i.e., omeprazole)	1 mg/kg/day twice daily	7–14
Amoxicillin ^a	50 mg/kg/day twice daily (max, 1 g twice daily)	7–14
Metronidazole	20 mg/kg/day twice daily (max, 500 mg twice daily)	7–14
Proton pump inhibitor ^b (i.e., omeprazole)	1 mg/kg/day	7–14
Quadruple Therapy		
Bismuth subsalicylate ^c	15 mL (17.5 mg/mL) four times daily	10–14
Metronidazole	20 mg/kg/day twice daily (max, 500 mg twice daily)	10–14
Tetracycline ^d	50 mg/kg/day twice daily (max, 1 g twice daily)	10–14
Proton pump inhibitor ^b (i.e., omeprazole)	1 mg/kg/day (max, 20 mg twice daily)	10–14
Amoxicillin ^a	50 mg/kg/day twice daily (max, 1 g twice daily)	10–14s
Clarithromycin	15 mg/kg/day twice daily (max, 500 mg twice daily)	10–14
Metronidazole	20 mg/kg/day twice daily (max, 500 mg twice daily)	10–14
Proton pump inhibitor (i.e., omeprazole)	1 mg/kg/day	10–14
Sequential Therapy		
First 5 Days		
Amoxicillin ^a	50 mg/kg/day twice daily (max, 1 g twice daily)	
Proton pump inhibitor (i.e., omeprazole)	1 mg/kg/day	
Second 5 Days		
Clarithromycin	15 mg/kg/day twice daily (max, 500 mg twice daily)	
Tinidazole	20 mg/kg/day bid (max, 500 mg bid)	
Proton pump inhibitor (i.e., omeprazole)	1 mg/kg/day	

^aIn patients allergic to penicillin, amoxicillin may be replaced with metronidazole.

^bComparable proton pump inhibitors such as lansoprazole and rabeprazole can be substituted at appropriate doses.

^cBismuth produces black stools and has the potential complication of salicylate toxicity. Salicylates also pose the risk for Reye syndrome.

^dTetracycline is not recommended for children younger than 8 years.

Modified from Gilger MA. Treatment of *Helicobacter pylori* infection in children. *Curr Pharm Des.* 2000;6:370–84; additional data from Gatta L, Vakli N, Leandro G, et al. Sequential therapy or triple therapy for *Helicobacter pylori* infection: systematic review and meta-analysis of randomized controlled trials in adults and children. *Am J Gastroenterol.* 2009;104:3069–79.

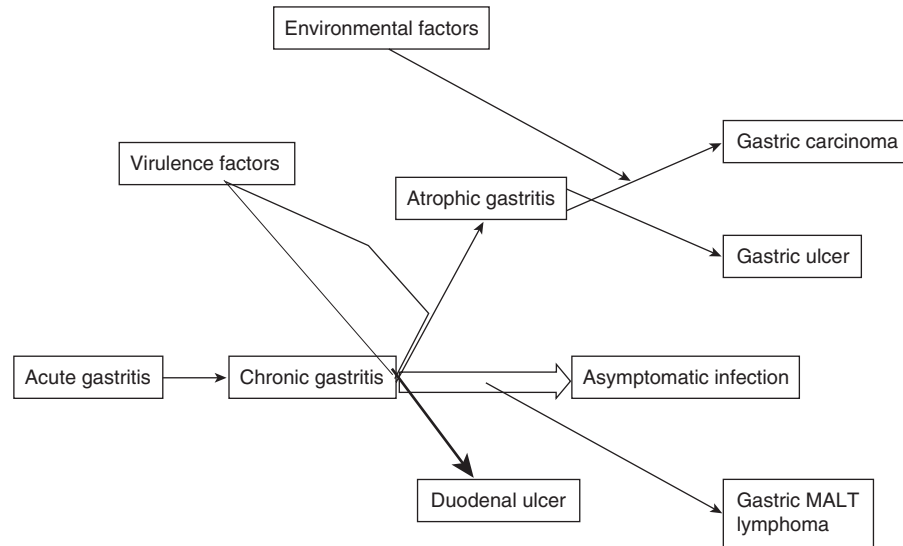

FIG. 135.5 Timeline of possible outcomes of *Helicobacter pylori* infection starting from the acute acquisition of infection and possible sequelae. MALT, Mucosa-associated lymphoid tissue. (Courtesy Dr. D. Graham, personal data.)

point mutations: A2143G, A2142G, and A2142C in domain V of 23S ribosomal RNA.^{45,134} Clarithromycin-containing therapy should be used if the area resistance rate is low (<10%).⁷³ Clarithromycin resistance rates of 15% to 20% should dissuade clinicians from using this drug. Increasing resistance has prompted newer treatment regimens, such as sequential therapy, which was shown to be superior to legacy triple therapy in treatment-naïve cases, as well as in clarithromycin-resistant and metronidazole-resistant cases.^{45,48,52,67,142} Sequential therapy consists of 5 days of a PPI and one antibiotic, usually amoxicillin, followed by 5 days of a PPI and two other antibiotics, such as clarithromycin and tinidazole (see Table 135.2). The general consensus is that if there is low clarithromycin resistance, clarithromycin-containing regimens and bismuth-containing regimens should be considered the first line of treatment.

Persistence and Resistance

Compliance and resistance are proven factors in the success or failure of a treatment regimen. Knowing the local susceptibilities and prevalence of antibiotic resistance allows for an increased rate of eradication and thus should be the guiding principle when choosing a treatment regimen.⁵⁸ Some developing countries, for example, have metronidazole resistance rates as high as 80%,⁶⁰ and pockets of Europe have clarithromycin resistance rates of 26%.⁹⁹ Therefore, treatment regimens should be regional specific. A clarithromycin resistance rate of 15% to 20% has been used to separate regions of high and low resistance.⁹²

The prevalence of clarithromycin resistance is on the rise and varies among countries and regions; in some instances, it is more common in children. Resistance has been associated with the endoscopic finding of an ulcer.⁹⁷

Methods of Testing Resistance

Gastric biopsy culture. Table 135.1 provides examples of gastric biopsy cultures.

Molecular methods. PCR is being used as an alternative to culture. PCR on gastric biopsies can detect mutations responsible for resistance to antibiotics such as clarithromycin and fluoroquinolone.^{80,98} Stool-based PCR testing has been shown to be as effective as and in some instances more effective than culture of gastric biopsies.^{131,135} Stool-based PCR sensitivities varies from 63% to 97% and specificity of 100% for *H. pylori* detection. Detection of clarithromycin resistance had a sensitivity of 83% and specificity of 100%.¹²² Oral-based PCR detection methods are also being studied.

Metronidazole, to which the *H. pylori* organism has been highly susceptible, has a high rate of resistance because of its overuse for

other infections.¹¹³ In cases of antimicrobial resistance, rifabutin, furazolidone,^{34,38,61,110,111,141} and fluoroquinolones, such as ciprofloxacin, along with rifampin and streptomycin, have been reported as options in treating resistant *H. pylori* infection.^{37,44,121} These second-line regimens have no particular advantage over the first-line antibiotics and should be considered only when drug resistance is suspected. No single antibiotic agent given alone provides effective therapy against *H. pylori*.^{114,120}

When cure of infection has been obtained, the long-term rates of reinfection are as low as 1% per year in developed countries but much higher in developing nations.¹⁰⁸ However, reinfection may be more likely to occur in families, especially when small children are the first infected.⁸ Hence, in recurrence, all family members should be tested. No conclusive evidence currently exists, however, to recommend routine treatment of the entire family.¹⁰³

Vaccination against *H. pylori* infection appears possible and also cost effective.^{19,29} Vaccination has cleared *H. pylori* infection in animal models.¹³⁶ Human models, however, have proved more difficult. The inactivated whole-cell *H. pylori* vaccine failed to eradicate preexisting infection.⁸⁶ Although the live-vector, urease-based vaccines did not completely clear all of the preexisting infections, they showed promise and demonstrated a T-cell-mediated response to infection.^{2,136} Success in human subjects was demonstrated with an antibody response to signaling, which is believed to regulate immune and inflammatory responses and has been shown to be important to the vaccine response.^{136,137} Despite this progress, the cellular response to bacterial colonization is not completely understood.¹²⁹ Prophylactic and therapeutic vaccination is needed because current antibiotic therapy does not eradicate *H. pylori* infection in approximately 20% of affected patients. Despite vaccination successes in treatment and prevention, the failure to achieve sterilization immunity in animal models has led to continued disease secondary to *H. pylori*. A truly effective vaccine has thus far remained elusive.¹⁰⁰

FUTURE DIRECTIONS

H. pylori is a major cause of peptic ulcer disease in children and adults, and this knowledge has caused a dramatic reappraisal of many previous notions about ulcer disease. Although the dictum “No acid, no ulcer” still holds, many other previous considerations, such as genetic predisposition, must be reexamined. Fig. 135.5 demonstrates a proposed *H. pylori* timeline. It emphasizes the acquisition of an acute infection in childhood, persistent chronic gastritis, and the possible progression to ulcer, atrophic gastritis, and, potentially, gastric carcinoma and lymphoma.

Treatment regimens that use local resistance data to achieve consistent eradication rates of 90% can eliminate disease burden. This burden includes gastric cancer; *H. pylori* is estimated to cause 89% of cases of noncardia gastric carcinoma.¹¹² To decrease the third most common cause of cancer death (gastric cancer), countries with a high disease burden could consider *H. pylori* screening and eradication programs to assess the overall impact on related cancer deaths as well as the economic burden of such an endeavor.⁶³

Kingella kingae

Eric A. Porsch • Joseph W. St. Geme III

Kingella kingae is being recognized increasingly as an important cause of invasive disease in young children, thus reflecting improved cultivation methods and new molecular diagnostics for this fastidious organism. Other members of the *Kingella* genus include *K. denitrificans*, *K. oralis*, and *K. potus*. *K. denitrificans* and *K. oralis* are commensals in the human oral cavity and are uncommon pathogens. *K. potus* is a commensal in the oral cavity of arboreal mammals and has been isolated from a human wound caused by an animal bite.⁶⁷

HISTORY

K. kingae was first isolated in 1960 from blood, joint fluid, bone exudates, and throat swabs by Elizabeth O. King, a bacteriologist at the Centers for Disease Control and Prevention. King's initial studies suggested that this organism was a novel *Moraxella* spp., thereby prompting shipment of samples to Henriksen and Bovre at the University of Oslo, Norway, for their opinion.⁵¹ Work by these investigators confirmed King's initial impressions and led to a publication describing the new species, which they named *Moraxella kingii* in honor of King.⁵¹ Additional studies in the late 1960s and 1970s established significant differences between *M. kingii* and other members of the *Moraxella* genus and resulted in reclassification as a novel genus and renaming of the organism as *Kingella kingae* in 1976.^{22,52}

Until the 1990s, *K. kingae* was largely ignored as a human pathogen because of its infrequent recovery in association with disease, generally in young patients with septic arthritis, osteomyelitis, or endocarditis.^{37,39,63,66,75,80,86,91,96} As novel culture-based isolation techniques were developed in the early 1990s,¹⁰⁸ the frequency of reported infections caused by *K. kingae* increased. Numerous studies using polymerase chain reaction (PCR)-based diagnostic techniques have shown that *K. kingae* is present in a significant percentage of culture-negative joint fluid and bone samples from patients with suspected osteoarticular infection.^{26,27,34,36,54,73,89,93,97} More recent evidence indicates that *K. kingae* is the leading cause of septic arthritis in children 6 to 36 months of age, more common even than *Staphylococcus aureus*.³⁶

MICROBIOLOGY

K. kingae is a gram-negative bacterium that belongs to the Neisseriaceae family and is only distantly related to other members of this family. It is a facultative anaerobic, β -hemolytic, small bacillus (0.6 to 1 $\mu\text{m} \times 1$ to 3 μm) that appears as pairs or short chains with tapered ends (Fig. 136.1) and often resists decolorization, thus sometimes resulting in misidentification as a gram-positive organism.^{51,98} *K. kingae* produces acid from glucose and maltose but not from other sugars and is oxidase positive and catalase, urease, and indole negative. Growth is supported on blood and chocolate agar but not on Krigler or MacConkey agar. Optimal growth occurs at 37°C (98.6°F) in a 5% to 10% carbon dioxide-enhanced atmosphere, but few strains are truly capnophilic.⁹⁸ Colonies from growth on solid agar appear as three distinct types: spreading/corroding, nonspreading/noncorroding, and domed.^{59,62,102} The spreading/corroding colony type produces marked indentations on the agar surface, develops a peripheral fringe around the small central raised colony, and is associated with high-density piliation. The nonspreading/noncorroding colony has a smaller fringe with a large, flat, central colony and is associated with low-density piliation. The domed colony produces no fringe and is nonpiliated.⁶² *K. kingae* is most easily differentiated from *K. denitrificans*, *K. oralis*, *K. potus*, and *Neisseria* spp. by a distinct narrow zone of β -hemolysis surrounding colonies on blood agar plates.

The partial or complete genome sequences of multiple *K. kingae* isolates are now publicly available. The genome size ranges from approximately 1.95 to approximately 2.15 megabases (Mb), has 46.6% to 46.8% GC content, and encodes approximately 1820 to approximately 2170 polypeptides (the range likely reflects the fact that some genomes are only partially sequenced). Genomic comparisons have revealed remarkably conserved synteny across *K. kingae* strains and an overall lack of synteny with other Neisseriaceae family members, a finding that highlights the classification of *K. kingae* as a unique taxonomic unit.^{47,58} With regard to extrachromosomal DNA, Banerjee and colleagues⁶ identified an approximately 15-kb R-plasmid and a 50-kb or greater

FIG. 136.1 Gram stain of *Kingella kingae* strain 269-492, a septic arthritis isolate. Scale bar = 10 μ m.

plasmid harboring a TEM-1 β -lactamase in 12 *K. kingae* strains. In addition, Rouli and colleagues⁸³ identified an approximately 15.5-kb plasmid encoding a TEM-1 β -lactamase and a streptomycin kinase in *K. kingae* strain KK247. Various studies have demonstrated that the *K. kingae* population structure is clonal.

To date, *K. kingae* has never been isolated from a nonhuman source, a finding suggesting that the organism is human specific.

EPIDEMIOLOGY

Carriage and Transmission

K. kingae is a human commensal that colonizes the posterior pharynx asymptotically in a subset of the population and occasionally invades the bloodstream to produce invasive disease. Using a novel vancomycin-containing medium developed in the early 1990s for isolation of *K. kingae* from the pharynx¹⁰⁸ or PCR assays, several studies have examined carriage rates in the healthy population.^{29,98,105,109,114} Based on studies conducted primarily in Israel and Europe, colonization with *K. kingae* begins at approximately 6 months of age and increases to a rate of 9% to 12% in children 12 to 24 months of age.^{3,29,45,105,109} The carriage rate gradually decreases in older persons, a finding suggesting that immune system development in healthy hosts may be responsible for upper respiratory tract clearance.^{105,109}

To achieve a better understanding of the transmission of *K. kingae* strains circulating in the community, multiple genotyping techniques have been developed, including pulsed field gel electrophoresis (PFGE),¹⁰⁹ random amplification of polymorphic DNA (RAPD),¹¹⁰ multilocus sequence typing (MLST),^{4,10,16} *por* gene sequencing,⁶ *rtxA* gene sequencing,^{4,16} and DNA uptake sequence typing (DUST).¹⁰ In a study that compared upper respiratory tract isolates from a cohort of healthy persons and a set of invasive isolates over a 15-year period,¹⁰⁹ genotypically indistinguishable strains were clustered in geographic regions and households, thereby suggesting person-to-person transmission among family members and close contacts. In agreement with this hypothesis, a study of intrafamilial oropharyngeal transmission revealed that 55% of patients with *K. kingae* osteoarticular infection and 40% of asymptomatic carriers had siblings who were colonized with *K. kingae*.⁵⁶ High rates of person-to-person transmission have also been documented in day care facilities.⁸⁸ In addition, many strains circulating among healthy persons matched historical strains recovered from sites of invasive disease, thus indicating that certain strains may persist in the population.¹⁰⁹

Yagupsky and colleagues¹¹⁰ examined paired isolates from the pharynx and bloodstream in three children with *K. kingae* bacteremia and found that the pharyngeal and blood isolates were genotypically identical in each case based on PFGE typing and RAPD; this finding provided evidence that colonization of the posterior pharynx is a precursor to

invasive disease. Similarly, Basmaci and associates¹³ reported isolation of *K. kingae* from the pharynx in children with confirmed *K. kingae* septic arthritis.

Ceroni and colleagues³¹ examined *K. kingae* oropharyngeal colonization density in healthy carriers and in children with invasive *K. kingae* disease by using real-time PCR and observed no differences. This finding suggested that colonization density does not directly influence the development of invasive *K. kingae* disease.

Invasive Disease

The most comprehensive study to date on the epidemiology of invasive disease was a multicenter study in Israel that examined a total of 321 cases of *K. kingae* disease.⁴⁰ In this report, 296 of the 321 pediatric cases involved children younger than 4 years of age, thus representing an annual incidence of 9.4 of 100,000 children from birth to 4 years of age. Only four cases involved children younger than 6 months of age.⁴⁰ Children younger than 4 years of age who were diagnosed with *K. kingae* disease were generally otherwise healthy,⁴⁰ whereas older children and adults who developed *K. kingae* disease usually had underlying predisposing conditions, including malignant disease, immunosuppression, or cardiac valve pathologic processes. The 321 total cases included 140 cases of septic arthritis, 19 cases of osteomyelitis, 7 cases of osteomyelitis with septic arthritis of the adjacent joint, and 3 cases of tenosynovitis, for a total 169 skeletal infections (53% of 321). The remaining cases included 140 cases of bacteremia without a focus (44% of 321), 4 cases of bacteremia and lower respiratory tract infection, and 8 cases of endocarditis.⁴⁰ Other reports have described *K. kingae* as a rare cause of pericarditis,⁷¹ meningitis,⁹² peritonitis,²¹ urinary tract infection,⁷⁹ and ocular infection.^{23,74}

Studies in France and Switzerland that used sensitive molecular approaches have added to our understanding of the epidemiology of *K. kingae* osteoarticular infection. In France, a 2-year prospective study of osteoarticular infections in children 15 years of age or younger found that *K. kingae* was present in the blood, bone, or joint samples in 52% of patients.⁴⁵ In Switzerland, a 3-year study of *K. kingae* carriage and invasive disease found the highest incidence of *K. kingae* disease in children 7 to 12 and 13 to 24 months of age and a progressively lower incidence in children between 24 and 48 months of age.⁵

In Israel, invasive *K. kingae* disease occurs throughout the year and is most common during November and December and least common between February and April.^{40,41} In contrast, the occurrence of carriage is more uniform throughout the year, a finding suggesting that the seasonal distribution of invasive *K. kingae* disease cannot be readily explained by the epidemiology of pharyngeal carriage. In Switzerland, invasive disease is most common in autumn, whereas carriage is roughly uniform throughout the year.⁵

The presence of two distinct pediatric populations serviced by the same medical system in southern Israel enabled Amit and colleagues¹ to study the epidemiology of *K. kingae* disease in this setting. Interestingly, the incidence of invasive disease in Westernized Jews (12.21 of 100,000) was significantly higher than the incidence of invasive disease in the Bedouin population (5.83 of 100,000). These findings differ from observations with other respiratory pathogens, such as *Streptococcus pneumoniae*, which have been shown to produce more morbidity in the Bedouin population.¹

In a study presenting findings in patients with *K. kingae* disease, Yagupsky and colleagues¹⁰⁹ found that approximately 50% of children display symptoms of upper respiratory tract infection, 15% to 20% have stomatitis, and 15% to 20% have diarrhea, thereby raising the possibility that concomitant viral infection contributes to development of invasive disease. In agreement with these findings, a study in France observed that 19 of 21 patients with proven *K. kingae* osteoarticular infection and only 3 of 8 patients with non-*K. kingae* osteoarticular infection had at least one respiratory virus present in throat swabs that were collected at the time of admission.¹² Using a PCR array to detect 18 different respiratory viruses, human rhinovirus (12 of 21), coronavirus OC43 (four of 21), parainfluenza virus 1, 2, 3, or 4 (three of 21), enterovirus (two of 21), and adenovirus (two of 21) were identified in the upper respiratory tract of patients with concurrent *K. kingae* osteoarticular infection.¹²

El Houmami and associates⁴⁴ described a series of nine *K. kingae* osteoarticular infections (five epidemic and four sporadic) in a French hospital occurring between April and October 2013. Of the seven patients younger than 24 months of age, five had antecedent hand, food, and mouth disease, and two had antecedent stomatitis. Both patients older than 24 months of age did not have evidence of oral manifestations. Retrospective analysis of an 11-month-old child who presented with arthritis with antecedent hand, food, and mouth disease revealed the presence of *K. kingae* DNA in stored joint fluid and coxsackievirus-A6 in a stored stool specimen.⁴⁴ These studies strongly support the hypothesis that upper respiratory tract viral infection contributes to the development of *K. kingae* invasive disease and suggest a possible link between the emerging European coxsackievirus-A6 epidemic and *K. kingae* disease.

Day Care Facility Attendance

A longitudinal study in Israel in the mid-1990s aimed to evaluate the transmission of *K. kingae* strains among day care facility attendees.⁸⁸ Fifty isolates were collected over an 11-month period by sampling two cohorts of day care facility attendees every 2 weeks. These isolates were compared with a collection of 60 epidemiologically diverse respiratory tract and invasive isolates. Based on a variety of typing techniques, children were found routinely to carry the same strain continuously or intermittently for weeks or months. Different strains were periodically able to replace the originally detected strain. Interestingly, a single strain represented 28% of the isolates and was most prevalent over the first 6 months of the study, and a different strain represented 46% of the isolates over the remaining 5 months.⁸⁸ Epidemiologically unrelated strains showed much greater variability in relatedness than isolates from the day care facility cohorts. A study examining the prevalence of *K. kingae* colonization in young children in Israel found that day care facility attendance is a risk factor for colonization.²

To date, 10 reports of day care facility outbreaks of invasive *K. kingae* disease have been described: two in the United States, two in France, and six in Israel.^{20,42,43,64,85,101,100,103,106} The first reported *K. kingae* outbreak occurred in Minnesota in 2003 and involved three cases of osteomyelitis or septic arthritis in children from the same classroom of 16- to 24-month-old children.⁶⁴ Carriage analysis of other attendees of the same facility revealed an overall colonization rate of 13% (15 of 122) and a peak colonization rate of 45% (nine of 20) in the classroom of 16- to 24-month-old children. All three children with invasive disease had concurrent or antecedent upper respiratory tract illness. In North Carolina in 2007, a case of confirmed *K. kingae* endocarditis and potential meningitis and a case of suspected intervertebral diskitis and osteomyelitis were identified in a 2-week period in children who attended the same day care facility.⁸⁵ A 2011 outbreak in France had an overall attack rate of 20.4% (5 of 24) and a carriage rate of 85% (11 of 13) among classmates available for sampling,²⁰ and a subsequent outbreak in 2013 had an attack rate of 23.8% (5 of 21) and a classmate carriage rate of 93.3% (14 of 15).⁴²

In Israel in 2005, one confirmed and two suspected cases of *K. kingae* skeletal infections were diagnosed in children from the same day care facility, and four of 11 classmates were colonized.¹⁰⁶ PFGE demonstrated that the pharyngeal and invasive isolates from the source day care facility were genotypically identical and that pharyngeal isolates from a control facility were genotypically distinct.¹⁰⁶ In 2012, one confirmed case of bacteremia and 1 presumed case of septic arthritis were identified in the same day care facility, with an overall classroom attack rate of 5.6% (two of 36) and a classmate carriage rate of 11.8% (four of 34).¹⁰¹

Another two cases of confirmed septic arthritis were identified in a classroom in a 2013 outbreak with an attack rate of 15.4% (two of 13) and a carriage rate among classmates of 45.4% (five of 11).¹⁰¹ In 2014, three additional outbreaks in Israel were identified.^{43,103} Each of these outbreaks had a classroom attack rate of 14.3% to 16.7% and a carriage rate among classmates of 33.3% to 58.3%.^{43,103} The 2005 and the three 2014 outbreaks in Israel occurred in so-called closed communities, with three outbreaks occurring on military bases and one occurring in a “kibbutz” commune, findings suggesting that the social communalities represented in these environments facilitate circulation of *K. kingae* among children in the susceptible age range.¹⁰³

FIG. 136.2 Transmission electron micrograph of type IV pili emanating from the surface of *Kingella kingae* strain 269-492. The sample was negatively stained with uranyl acetate. Scale bar = 100 nm.

PATHOGENESIS AND IMMUNITY

The pathogenesis of disease caused by *K. kingae* is believed to begin with colonization of the posterior pharynx.^{98,111} The process of colonization likely involves adherence to respiratory epithelial cells, which is mediated in part by polymeric surface pili (Fig. 136.2).⁵⁹⁻⁶¹ *K. kingae* pili are classified as type IV pili and are composed primarily of a major pilin subunit, PilA1.⁶⁰ In addition, *K. kingae* pili contain two pilus-associated proteins, called PilC1 and PilC2, that appear to play complementary roles in promoting pilus assembly and in mediating adherence to respiratory epithelial cells.⁶⁰ PilC1 and PilC2 differentially modulate type IV pili-mediated twitching motility because PilC1 mediates robust motility through a calcium ion binding-dependent mechanism, and PilC2 mediates modest twitching motility through a calcium ion binding-independent mechanism.⁷⁷ Consistent with the conclusion that pili promote *K. kingae* colonization, examination of a collection of pharyngeal isolates of *K. kingae* demonstrated that most are pilated and express abundant pili.⁶¹

K. kingae also produces a nonpilus adhesive protein called Knh, which is essential for full-level adherence to cultured respiratory epithelial cells.⁷⁸ Knh shares homology with the *Neisseria meningitidis* NhxA adhesin and belongs to the trimeric autotransporter family of proteins. Like other trimeric autotransporters, Knh has an N-terminal signal sequence, a characteristic C terminus, and a modular internal passenger domain that is ultimately surface localized. The passenger domain contains a series of 19 YadA-like head domains with similarity to the β -roll that has been implicated in the adhesive activity of the *Yersinia* YadA trimeric autotransporter and a stalk that contains seven Trp ring domains, three neck domains, three KG domains, and an iSneck2 domain. Disruption of the gene encoding Knh results in an approximately 50% decrease in adherence in *in vitro* assays.⁷⁸ A study by Rempe and colleagues⁸¹ demonstrated that Knh is modified with hexose residues by an unconventional N-linking glycosyltransferase and that glycosylation is essential for the adhesive properties of the protein.

After colonization of the posterior pharynx, *K. kingae* must translocate across the pharyngeal epithelium to enter the bloodstream. Given that patients with invasive *K. kingae* disease frequently have manifestations of viral respiratory tract infection, evidence of herpetic gingivostomatitis, or signs of aphthous stomatitis, it is possible that virus-induced damage to the respiratory mucosa facilitates *K. kingae* invasion of the bloodstream.^{42,44,98,111} Beyond the role of viral coinfection, *K. kingae* produces a potent extracellular toxin that belongs to the RTX (repeat in toxin)

family of toxins and is capable of lysing epithelial, synovial, and macrophage cells.⁶² In vitro studies have shown that the RTX toxin is able to form 1.9-nm pores in artificial membranes and can be delivered to host cells by outer membrane vesicle secretion.^{7,70} By using an infant rat infection model, an isogenic RTX-deficient mutant was shown to be attenuated in virulence compared with the parental strain, a finding suggesting that the toxin may play a role in the pathogenesis of *K. kingae* invasive disease.³³ This toxin may facilitate disruption of the respiratory epithelium, perhaps with an increased effect in the setting of viral coinfection. The *K. kingae* RTX locus resembles the RTX locus in *Moraxella bovis* and *N. meningitidis* and was likely acquired through horizontal transfer.⁶²

Once in the bloodstream, *K. kingae* must be able to evade a variety of host defense mechanisms. Similar to other bacterial pathogens that produce bacteremic disease in children, *K. kingae* produces an extracellular polysaccharide capsule (Fig. 136.3).^{17,78,90} By analogy to other encapsulated bacteria, encapsulation of *K. kingae* may facilitate resistance to serum killing activity and opsonophagocytosis and thereby promote intravascular survival and dissemination to distant sites.¹¹¹ Analysis of a large collection of invasive and carrier isolates revealed a total of four different capsule types: type a (polymer of GalNAc-Kdo), type b (polymer of GlcNAc-Kdo), type c (polymer of ribose-Kdo), and type d (polymer of GlcNAc-galactose). Interestingly, strains expressing the type c or type d capsule are almost exclusively carrier isolates, and strains expressing the type a and type b capsules account for approximately 96% of invasive disease isolates; this finding suggests that the latter two capsule types may play a role in the development of *K. kingae* invasive disease.^{116,117} In addition to the capsular polysaccharide, *K. kingae* has been shown to secrete a linear galactofuranose exopolysaccharide with antibiofilm activity.^{17,90}

In patients in whom *K. kingae* is able to persist in the bloodstream, the organism may produce uncomplicated bacteremia or may instead disseminate to joints, bones, or the endocardium.^{98,111} Analysis of a large collection of *K. kingae* systemic isolates demonstrated that strains recovered from the blood of patients with uncomplicated bacteremia were generally piliated but typically expressed relatively few pili.⁶¹ In contrast, strains recovered from joint fluid, bone aspirates, or the blood of patients with endocarditis were generally nonpiliated.⁶¹ It is possible that low-density piliation facilitates a tropism for joints, bones, and the endocardium and potentiates an inflammatory response, which then selects against piliated organisms. Consistent with this possibility, pili promote efficient adherence to cultured synovial cells. Similar to type IV pili expressed by other pathogens, *K. kingae* pili are regulated by a

transcription factor called $\sigma 54$ and by a two-component sensor/regulator system termed PilS/PilR.⁶⁰ Mutations in the PilS sensor result in a reduced density of pili, similar to the relative decrease in density of pili in isolates recovered from the bloodstream in contrast to the posterior pharynx. Conversely, mutations in the PilR response regulator result in elimination of piliation, similar to the absence of pili in isolates from joints and bones.⁶⁰ It is unclear which environmental factors influence $\sigma 54$, PilS, and PilR activity and control the density of *K. kingae* piliation. The three different colony morphologies that are detectable on agar plates and correlate with the level of piliation may reflect mutations in PilS and PilR.⁶¹

To investigate the role of the host immune system in development of *K. kingae* disease in healthy persons, Slonim and colleagues⁸⁷ examined serum immunoglobulin (Ig) A and IgG levels against outer membrane proteins in 19 children with invasive disease. As expected, children convalescing from invasive disease had significant increases in IgA and IgG levels. Further analysis has demonstrated that the age incidence of disease is inversely correlated with serum IgA and IgG levels in healthy persons. Infants younger than 6 months of age have undetectable serum IgA but high serum IgG levels, a finding suggesting that protection from invasive disease in this age group results from maternally derived IgG.⁸⁷ Children between 6 and 18 months of age have the highest age incidence of disease and the lowest serum IgG levels.⁴⁰ Children 24 months of age and older have a progressively decreasing incidence of disease and progressively increasing IgG and IgA levels, thus suggesting that carriage or exposure to *K. kingae* during the first 2 years of life may be an immunizing event. However, *K. kingae* outer membrane protein epitopes are polymorphic from strain to strain; this property raises the possibility that the immune response is strain specific and may not prevent recolonization by an antigenically distinct strain.¹¹²

CLINICAL MANIFESTATIONS

Osteoarticular Infections

Septic arthritis caused by *K. kingae* is monoarticular and most often involves the knee, hip, or ankle.⁹⁸ Other joints that may be affected include the wrist, shoulder, elbow, sternoclavicular, metacarpophalangeal, and tarsal joints. Fever is present in approximately 85% of patients with *K. kingae* arthritis. Arthrocentesis reveals purulent synovial fluid with a mean white blood cell count of approximately 130,000/mm³ (range ~5000–300,000/mm³) and a differential that contains more than 90% neutrophils.⁴¹ Other laboratory measurements include a mean peripheral white blood cell count of 14,800/mm³ (range, 6000–28,450/mm³), a mean C-reactive protein of 3.7 mg/dL (range, 0.2–17.0 mg/dL), and a mean erythrocyte sedimentation rate of 44.1 mm/h (range, 5–140 mm/h).³⁹

Osteomyelitis resulting from *K. kingae* usually involves long bones such as the femur and tibia.⁹⁸ However, *K. kingae* also has an unusual predilection to produce disease in small bones, including the calcaneus and talus.^{40,98} Children with *K. kingae* osteomyelitis often present with a limp and have a significantly more prolonged course of symptoms before presentation in contrast to patients with septic arthritis (9.2 ± 9.4 vs. 3.2 ± 3.0 days). Laboratory measurements include a mean peripheral white blood cell count of 13,888/mm³ (range, 5860–2,000/mm³), a mean C-reactive protein of 1.8 mg/dL (range, 0.2–4.3 mg/dL), and a mean erythrocyte sedimentation rate of 40.0 mm/h (range, 12–85 mm/h).⁴⁰

Among patients younger than 4 years of age with spondylodiskitis, at least one-fourth have *K. kingae* infection.^{28,32,48} In order of frequency, infection involves the lumbar, thoracolumbar, cervical, thoracic, and lumbosacral intervertebral spaces. Patients with *K. kingae* spondylodiskitis can have a limp, back pain, refusal to sit or walk, or neurologic symptoms, but the symptoms are often mild. Fever is present in two-thirds of patients but rarely exceeds 39°C (102.2°F). Other skeletal infections caused by *K. kingae* include dactylitis³⁵ and tenosynovitis.^{42,44,98}

K. kingae bacteremia without evidence of endocarditis or other localizing signs is being increasingly recognized in young children. The duration of symptoms before diagnosis ranges from 1 to 7 days, and the mean maximal fever is 39°C (102.2°F).^{41,98} Occasional patients have a maculopapular rash resembling the rash in early meningococcal or gonococcal infection.^{49,91} Laboratory evaluation often reveals an elevated

FIG. 136.3 Transmission electron micrograph of thin-sectioned, cationic ferritin-stained *Kingella kingae* strain 269-492. The dark layer of electron density on the surface of the bacteria is caused by cationic ferritin interacting with the polysaccharide capsule. Scale bar = 500 nm.

peripheral white blood cell count (mean, 12,700/mm³; range, 7120–47,040/mm³), modest elevation of C-reactive protein (mean, 2.2 mg/dL, range 0.6–13.4 mg/dL), and significant elevation of erythrocyte sedimentation rate (mean 50 mm/h; range, 14–115 mm/h).⁴⁰

K. kingae is included in the HACEK (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella* spp.) group of bacteria accountable for 3% to 5% of cases of bacterial endocarditis. In contrast to other *K. kingae* infections, *K. kingae* endocarditis is most common in older children and adults.⁹⁸ In approximately 50% of cases, infection involves a native valve, often related to a predisposing cardiac malformation or rheumatic heart disease.^{18,76,82,95,98,115} Disease usually involves the left side of the heart, most often the mitral valve.^{98,111} Patients with *K. kingae* endocarditis typically have fever and elevated C-reactive protein and erythrocyte sedimentation rate.⁴⁰ Complications can be severe and include congestive heart failure, septic shock, mycotic aneurysm, pulmonary infarction, meningitis, and stroke, and the overall mortality rate is approximately 16%.^{18,46,53,68,82,85,95,115}

DIAGNOSIS

The recovery of *K. kingae* from purulent specimens seeded onto solid culture media is poor, often resulting in a lack of growth. The yield of cultures is improved significantly by inoculating specimens into Isolator 1.5 microbial tubes or aerobic blood culture vials from a variety of automated blood culture systems such as BacTec, BacT/Alert, and Hemoline DUO.⁹⁸ When positive blood culture vials are subcultured onto routine solid media, *K. kingae* grows readily, a finding suggesting that exudates may inhibit growth and that dilution of purulent material in a large volume of broth may decrease the concentration of inhibitory factors, thereby improving the recovery of this fastidious organism.⁹⁸ In studies in which blood culture vials were routinely used for culturing synovial fluid aspirates from young children with suspected joint infections, *K. kingae* was isolated in almost one-half of the patients who ultimately had culture-proved bacterial disease.^{73,102} Matrix-assisted laser desorption ionization–time of flight mass spectrometry has been shown to be effective for the identification of *K. kingae*.³⁸

Studies published since the 1990s have demonstrated that PCR dramatically enhances detection of *K. kingae* in bone and joint fluid samples in contrast to routine cultures and blood culture vials. Some studies have used universal 16S rRNA primers,^{24,72,89} and others have used specific primers that amplify either the *K. kingae* *cpn60* gene³⁶ or the *K. kingae* *rtxA* gene.^{24,27,34,54,69,72} As an example, Chometon and coworkers³⁶ sequentially analyzed bone and joint samples by using blood culture vials, conventional PCR with universal primers, and real-time PCR with primers derived from the *K. kingae* *cpn60* gene and achieved a *K. kingae* detection rate that increased from 29% of all microbiologically proved cases with blood culture, to 41% with conventional PCR with universal primers, to 45% with *K. kingae*-specific PCR, thus accounting for approximately 80% of microbiologically proved cases in children younger than 3 years of age.³⁶ *K. kingae*-specific PCR approaches are typically more sensitive than PCR assays using broad-range 16S rRNA primers.

Given the fastidious nature of *K. kingae* and the difficulty in isolation of the organism from the blood and sites of infection, the clinical value of oropharyngeal PCR detection of *K. kingae* in pediatric patients with suspected osteoarticular infection has been investigated.^{25,30} During a 3-year prospective study in a Swiss hospital, a total of 10 patients 6 to 48 months of age had magnetic resonance imaging evidence consistent with spondylodiskitis. Each patient presented with mild to moderate clinical symptoms and inflammatory responses, and all blood culture results were negative. PCR detection of *K. kingae* in peripheral blood was positive in 20% (two of 10) of the patients, but PCR analysis of oropharyngeal swabs was 100% (10 of 10) positive; these results provided reasonable suspicion that *K. kingae* was responsible for the spondylodiskitis.²⁵

In a separate study, 123 6- to 48-month-old patients with osteoarticular complaints were screened for oropharyngeal *K. kingae*.³⁰ Forty patients met the case definition of osteoarticular infection: 30 had *K. kingae* osteoarticular infection, one had another organism, and nine had no microbial diagnosis. All 30 patients with *K. kingae* osteoarticular infection, and eight of the 84 patients without osteoarticular infection or with osteoarticular infection caused by another organism tested

positive for oropharyngeal *K. kingae*, thus resulting in a sensitivity of 100% and a specificity of 90.5%.³⁰ All nine patients with osteoarticular infection with no microbial diagnosis tested positive for oropharyngeal *K. kingae*, were treated for *K. kingae* osteoarticular infection, and demonstrated clinical improvement after treatment.³⁰

Plain radiographs often complement culture and PCR-based diagnostic methods; they demonstrate soft tissue swelling and joint effusions in approximately 50% of patients with septic arthritis and show lytic lesions or disk space narrowing in 95% of cases of osteomyelitis or spondylodiskitis.⁹⁸ Technetium-99m bone scans may be helpful in diagnosing *K. kingae* osteomyelitis during the early course of disease, before abnormalities are present on plain radiographs.^{48,49} Echocardiography is helpful in diagnosing *K. kingae* endocarditis and often reveals large vegetations, especially in patients who have had symptoms for a prolonged period or have clinical evidence of embolization.

Given that gram-positive cocci such as *S. aureus* and *Streptococcus pyogenes* are the other main pathogens responsible for osteoarticular infections in the pediatric population, several studies have investigated various approaches to distinguish infection with these organisms from infection with *K. kingae*. Because of the typically mild to moderate clinical and biologic features of *K. kingae* osteoarticular infection compared with osteoarticular infection caused by gram-positive cocci, Ceroni and colleagues²⁶ proposed a predictive score system using four variables: body temperature lower than 38°C, serum C-reactive protein lower than 5.5 mg/L, white blood cell count lower than 14,000/mm³, and band forms lower than 150/mm³. In their study population, a total of 96.7% of patients with *K. kingae* osteoarticular infection met at least three criteria, whereas only 10% of patients with other pathogens met at least three criteria. However, Basmaci and colleagues^{14,15} found that this scoring system was not able to distinguish between *K. kingae* and *S. aureus* osteoarticular infection effectively in a different study population, and the only significant differentiating factor was younger age for the patients with *K. kingae* osteoarticular infection. Simultaneous targeted *K. kingae* and *S. aureus* real-time PCR on synovial fluid samples was shown to be effective in detecting *K. kingae* but was less sensitive than culture in detecting *S. aureus*.⁵⁰ A study comparing the early magnetic resonance imaging characteristics of osteoarticular infection caused by *K. kingae* versus gram-positive cocci found that bone reaction was less frequent and soft tissue reaction was less severe in infection with *K. kingae*.⁵⁷ In addition, epiphysis cartilage abscesses were present only in *K. kingae* osteoarticular infection.⁵⁷

TREATMENT

K. kingae is almost always susceptible to second- and third-generation cephalosporins, aminoglycosides, macrolides, trimethoprim-sulfamethoxazole, tetracyclines, fluoroquinolones, and chloramphenicol.^{55,65,98,107} Most *K. kingae* isolates are susceptible to penicillins, although in vitro susceptibility to oxacillin is relatively reduced. There are increasing reports of β -lactamase production with varying degrees of activity.^{11,55,65,99,105,113} Two studies described a series of *K. kingae* isolates with relatively low-level β -lactam resistance; one study reported minimum inhibitory concentrations of 0.094 to 2 μ g/mL for penicillin,¹¹³ and the other study reported minimum inhibitory concentrations of 0.25 to 8 μ g/mL for amoxicillin.¹¹ Studies have revealed that the TEM-1 β -lactamase can also be chromosomally or plasmid encoded in *K. kingae*.^{8,9,19} Between 40% and 100% of isolates are resistant to clindamycin,^{99,107} and virtually all isolates are resistant to trimethoprim and glycopeptide antibiotics, including vancomycin.^{41,107}

Given the lack of controlled studies, no detailed guidelines for preferred antibiotic and length of treatment course have been developed for *K. kingae* infections. Typically, treatment varies based on accepted measures for other pathogens. Given the reduced susceptibility of many *K. kingae* isolates to oxacillin and clindamycin and the increasing recognition of β -lactam resistance, administration of a β -lactamase-resistant penicillin or a second-generation or third-generation cephalosporin is appropriate for suspected skeletal infections while laboratory results are pending.^{94,99,98} In areas where methicillin-resistant *S. aureus* is common, addition of vancomycin is recommended.⁸⁴ Once *K. kingae* is identified and β -lactam resistance is excluded, antibiotic therapy is commonly

changed to amoxicillin or cefuroxime. The switch from intravenous to oral antibiotic therapy should be evaluated based on clinical response and assessment of acute-phase reactants such as C-reactive protein.

The length of antibiotic treatment for *K. kingae* disease has varied based on specific type of infection. Treatment has generally varied from 2 to 3 weeks for *K. kingae* arthritis, from 3 to 6 weeks for *K. kingae* osteomyelitis, and from 3 to 12 weeks for *K. kingae* spondylodiskitis.⁹⁸ Patients with septic arthritis usually respond well to antibiotic therapy and do not require repeated joint aspirations or invasive surgical procedures.⁹⁸

Patients with *K. kingae* bacteremia typically have a relatively benign course and are usually treated initially with an intravenous β -lactam antibiotic and are then switched to oral therapy once the clinical condition has improved. Antibiotic therapy is generally continued for a total of 1 to 2 weeks.¹⁰⁴

Children with *K. kingae* native valve endocarditis are usually treated intravenously with a β -lactam agent alone or in combination with an aminoglycoside.⁹⁸ Typically, the length of treatment is 4 to 7 weeks.⁹⁸ Because of the potential risk for life-threatening valve damage resulting from endocarditis, patients who do not respond to antibiotic therapy may require early surgical intervention.^{82,95,115}

PREVENTION

In the reported cases of day care outbreaks, oral antibiotics were administered to contacts of the infected children to prevent further spread. The antibiotic courses varied and included either rifampin, 2 mg/kg up to 600 mg per dose twice daily for 2 days; rifampin, 10 mg/kg twice daily for 2 days²⁰; a combination of rifampin, 10 mg/kg and amoxicillin, 40 mg/kg twice daily for 2 days⁸⁵; or a combination of rifampin, 20 mg/kg twice daily for 2 days and amoxicillin, 80 mg/kg twice daily for 4 days.¹⁰⁶ A wide range of antibiotic prophylaxis efficacy has been reported. For example, a combination of rifampin, 20 mg/kg twice daily for 2 days, and amoxicillin, 80 mg/kg per day for 2 days, was prescribed to classroom contacts in three Israeli day care facility outbreaks for which postprophylactic treatment carriage rates were reported. In two of these outbreaks, complete eradication of carriage in contacts (4 of 11 to 0 of 11¹⁰⁶ and 5 of 11 to 0 of 11¹⁰¹) was reported, and in the other outbreak the carriage rate was reduced from 11.8% (4 of 34) to 5.6% (2 of 36).¹⁰¹ Treatment with only rifampin, 10 mg/kg up to 600 mg per dose twice daily for 2 days, appears less efficacious, with one study showing a 0% reduction of colonized contacts after prophylaxis²⁰ and another study showing only a 14.2% reduction in colonized contacts after prophylaxis.⁴²

Currently no measures are available to prevent *K. kingae* infection in the general population. Given that *K. kingae* expresses a capsular polysaccharide,^{17,78} it is possible that a polysaccharide-conjugate vaccine would be a viable approach to prevention of disease, similar to the situation with *Haemophilus influenzae* type b, *S. pneumoniae*, and *N. meningitidis*. The observation that two capsule types account for more than 95% of invasive disease isolates suggests that the development of a polysaccharide-conjugate vaccine may be a feasible strategy to prevent *K. kingae* disease.
